NATIONAL LIBRARY OF SCOTLAND

In Quarto, cloth, Price 24s.

ENCYCLOPEDIA BRITANNICA

Eighth Edition. VOL. XIV.

ILLUSTRATED BY NUMEROUS ENGRAVINGS.

PRINCIPAL CONTENTS:

MAGNETISM, MICROMETER, and MICROSCOPE. By Sir DAVID BREWSTER, K.H., &c.

MAMMALIA. By JAMES WILSON, Author of the article "Entomology."

MANCHESTER. By THOMAS BAZLEY, Chairman of the Chamber of Commerce, Manchester.

MANUFACTURES. By J. R. M'CULLOCH.

MECHANICS. By W. J. M. RANKINE, Professor of Civil Engineering and Mechanics in the University of Glasgow.

MEDICAL JURISPRUDENCE. By T. S. TRAILL, M.D., Professor of Medical Jurisprudence in the University of Edinburgh.

MEDICINE. By THOMAS LAYCOCK, M.D., Professor of the Practice of Physic in the University of Edinburgh.

MENSURATION. By WILLIAM SWAN, Lecturer on Mathematics and Natural Philosophy.

MENTAL DISEASES. By DAVID SKAE, M.D., Physician to the Royal Edinburgh Asylum.

METAPHYSICS. By Rev. H. L. MANSEL, Reader in Moral and Metaphysical Philosophy, Magdalen College, Oxford.

METEOROLOGY. By Sir JOHN F. W. HERSCHEL, Bart., K.H., M.A., D.C.L., &c.

Edinburgh: ADAM & CHARLES BLACK. London: SIMPKIN, MARSHALL, & Co.;
and all Booksellers.

MAGNETISM.

History.

The word magnetism is derived from the Greek word μάγνης, a name given to the *loadstone*, or *native magnet*, an ore of iron well known to the ancients. The term μάγνης itself is said to be derived from one *Magnes*, a Greek shepherd, who observed on Mount Ida the attractive power which the loadstone exercised upon his iron crook. The most probable supposition, however, is that it took its name from *Magnesia*, a country in Lydia, where it was first discovered; and this conjecture is confirmed by the fact that the magnet was often called by the ancients *Lapis Heracleus*, from *Heraclea*, the capital of *Magnesia*.

The science of magnetism treats of the phenomena exhibited by magnets, whether natural, like the loadstone, or artificial, like bars of steel to which magnetism has been permanently communicated; of their reciprocal action upon each other; of the laws of the forces which they develop; of the methods of making artificial magnets; and of the magnetic phenomena exhibited by our globe.

In giving an account of this interesting science in modern times, we shall adopt the following arrangement:—

1. On the history of magnetical discovery.
2. On the general phenomena and principles of natural and artificial magnets.
3. On the magnetism of bodies not ferruginous.
4. On the development of magnetism in bodies by rotation.
5. On the influence of heat on magnetism.
6. On the action of iron spheres on the needle.
7. On the influence of magnetism on chemical action.
8. On the laws of magnetic forces.
9. On terrestrial magnetism.
10. On the different methods of making artificial magnets.
11. On magnetical instruments and apparatus.
12. On the theories of magnetism.

CHAP. I.—ON THE HISTORY OF MAGNETICAL DISCOVERIES.

The attractive power of the natural magnet or loadstone over small pieces of iron seems to have been known from the remotest antiquity. It is distinctly referred to by Homer, Pythagoras, and Aristotle. Pliny mentions a chain of iron rings suspended from one another, the first being upheld by the loadstone; and he relates that Dinocares proposed to Ptolemy Philadelphus to build at Alexandria a temple, the vault of which, crowned with loadstones, should suspend in the air an iron statue of Queen Arsinöe. St Augustin likewise makes mention of a statue suspended in the air in the temple of Serapis at Alexandria.

History.

Invention of the compass.

In his description of China, Duhalde has stated that the directive power, or polarity of the magnet, was known to the Chinese in the earliest ages, and that the needle had been employed to guide travellers by land a thousand years before Christ; and it is stated by Humboldt, that, according to the *Peuthsaoyani*, a treatise on Medical Natural History, written 400 years before Columbus, the Chinese suspended the needle by a thread, and found it to decline to the S.E., and never to rest at the true S. point.

Although the common properties of the loadstone were known to the ancients, and were no doubt studied even during the dark ages, yet, notwithstanding the claims of the Chinese and Arabians, the directive power of the loadstone, or of a needle touched or rubbed by it, seems to be the discovery of modern times. Are Frode, an Icelandic historian, who was born in 1068, mentions in his *History of the Discovery of Iceland*, that Floke Vilgerderson departed from Rogoland, in Norway, to seek Gadersholm, or Iceland, some time in the year 868. He carried with him three ravens as guides; and, to consecrate them for this purpose, he offered up a sacrifice in Smörsund, where his ship lay. "*For*," says Frode, "*in those times seamen had no loadstone in the northern countries.*" A.D. 868.

A Chinese philosopher, Keoutsoung-chy, who wrote works on natural history about A.D. 1111, observes, that the magnetic needle declines towards the E., and is $\frac{5}{6}$ths to the S.

That the mariner's compass was known in the twelfth century, about the year 1150, is proved by notices of it in various authors, particularly in an old French poem called *La Bible Guyot*, which is contained in a curious quarto manuscript of the thirteenth century, still existing in the Royal Library at Paris. Guyot of Province, the author of this poem, was alive in 1181. After referring to the ways by which navigators are guided in their course, and mentioning the pole star, he adds,—

Un art font qui mentir ne peut,
Par la vertue de la marinière,
Un pierre laide et brunière
Où le fers volontiers se joint,
Ont regardent lor droit point.

A.D. 1200.

Cardinal James de Vitri, who flourished about the year 1200, mentions the magnetic needle in his history of Jerusalem; and he adds, that it was of indispensable utility to those who travelled by sea.

That the mariner's compass was known to the northern nations in 1266, appears from Torfæus's *History of Norway*, where it is mentioned, that Jarl Sturla's poem on the death of the Swedish count Byrgeres was rewarded with a mariner's compass. The directive property of the magnet is also distinctly mentioned in an epistle of Petrus Peregrinus de Marcourt, written about the latter end of the thirteenth century. This letter was addressed "Ad Sigerium de Foueancourt militem de magnete." This epistle contains a description of the loadstone, the means of finding its poles, and its property of attracting iron; and it proves that *the part of the magnet which is turned to the N. attracts that which is turned to the S.*

Paulus Venetus. A.D. 1260.

Peter Adsiger. A.D. 1269.

A Neapolitan, named Flavio Gioia, who lived in the thirteenth century, has been regarded by many as the inventor of the compass. Dr Gilbert affirms that Paulus Venetus brought the compass from China to Italy in 1260. Ludi Vestomannus asserts, that about 1500 he saw a pilot in the East Indies direct his course by a magnetic needle like those now in use. One of the earliest treatises on magnetism is a Latin letter of Peter Adsiger, written in 1269, contained in a volume of manuscripts in the library of the University of Leyden. This letter, which appears to have been written for the instruction of a friend, is in reality a methodical treatise, in two parts, the first of which is subdivided into ten, and the second into three chapters. In the second chapter of the second part, the mariner's compass, and the method of constructing it, are clearly described; and, what is still more interesting, the author not only mentions the declination of the magnetic needle, but had observed its actual deviation from the meridian. "Take notice," says he, "that the magnet, as well as the needle which has been touched by it, does not point exactly to the poles; but that part of it which is reckoned to point to the S. inclines a little to the W., and that part which looks towards the N. inclines as much to the E. The exact quantity of this declination I have found, after numerous experiments, to be *five degrees*. However, this declination is no obstacle to our guidance, because we make the needle itself decline from the true S. by nearly one point and a half towards the W. A point, then, contains five degrees." Mr Christie seems to consider the authenticity of this manuscript as doubtful, because no new observation of the declination seems to have been made for two centuries afterwards; and because the declination should be westerly in place of easterly in 1269, according to the best law of the change which can be deduced from subsequent observations.

Columbus. A.D. 1492.

Variation discovered.

The declination, or the variation of the needle, thus distinctly described by Adsiger, if his manuscript is authentic, must be considered as well known before the time of Columbus, to whom the discovery of it has been generally ascribed. His son Ferdinand states, that on the 14th of September (13th according to Washington Irving) 1492, his father, when about two hundred leagues from the island of Ferro, noticed for the first time the variation of the needle; "a phenomenon," says Irving, "which had never before been remarked." "He perceived," adds this author, "about nightfall, that the needle, instead of pointing to the N. star, varied but half a point, or between five and six degrees to the N.W., and still more on the following morning. Struck with this circumstance, he observed it attentively for three days, and found that the variation increased as he advanced. He at first made no mention of this phenomenon, knowing how ready his people were to take alarm; but it soon attracted the attention of the pilots, and filled them with consternation. It seemed as if the laws of nature were changing as they advanced, and that they were entering another world, subject to unknown influences. They apprehended that the compass was about to lose its mysterious virtues; and, without this guide, what was to become of them in a vast and trackless ocean? Columbus tasked his science and ingenuity for reasons with which to allay their terrors. He told them that the direction of the needle was not to the polar star, but to some fixed and invisible point. The variation was not caused by any failing in the compass, which, like the other heavenly bodies, had its changes and revolutions, and every day described a circle round the pole. The high opinion that the pilots entertained of Columbus as a profound astronomer gave weight to his theory, and their alarm subsided."[1] Although the details which we have already given afford sufficient proof that the variation of the needle had been discovered two hundred years before the time of Columbus, yet it is evident, from the above passage, that he had discovered the variation of the variation, or that the variation was not a constant quantity, but varied in different latitudes.

Change in the variation.

Norman.

Burough.

Notwithstanding these casual observations on the variation of the compass, no accurate measures of its amount were made till about the middle of the sixteenth century. In 1541 it was found that the declination of the needle from the meridian of Paris was about 7° or 8° easterly. In 1550 it was 8° or 9°, and in 1580, 11½° easterly. Norman,[2] who first observed the variation in London, made it 11° 15′ easterly; and Mr Burough,[3] comptroller of the navy, in 1580 found it to be at an average 11° 19′ E. at Limehouse. The following observations made at other places will show the gradual change in the variation:—

Burough	1580	11°	19′	E. Limehouse.
Gunter	1612	5	36	E. London.
Gellibrand[4]	1633	4	4	E. London.
Petit	1630	4	30	E. Paris.
Petit	1660	0	10	E. Paris.
Auzout	1670	2	0	W. Rome.
Hevelius	1642	3	5	W. Dantzig.
Hevelius	1670	7	20	W. Dantzig.

Dip of the needle discovered by Norman, A.D. 1576.

The important discovery of the *dip* or inclination of the needle was made in 1576, by Robert Norman, whom we have already mentioned. Having constructed many compasses, and having always balanced the needles for them before he touched them with the magnet, he invariably found, that after they were touched the north point always inclined below the horizon, so that he was obliged to make the card of the compass level by putting some small pieces of wire on the end of it. Having mentioned this discovery to some of his friends, he was advised to construct an instrument which would enable him to measure the greatest angle which it would make with the horizon. With this instrument, which is the dipping needle in its first and rudest form, he found the dip to be at 71° 50′; an observation which, according to Bond, must have been made about 1576.

J. Cæsar.

That ferruginous substances always possess a greater or a less degree of magnetism, has been long known. One Julius Cæsar, a surgeon of Rimini, first observed the conversion of iron into a magnet. In 1590 he noticed this effect on a bar of iron which had supported a piece of brick-

Gassendi.

work on the top of a tower of the church of St Augustin. The very same fact was observed about 1630 by Gassendi, on the cross of the church of St John at Aix, which had fallen down in consequence of having been struck with lightning. He found the foot of it wasted with rust, and possessing all the properties of a loadstone.

Dr Gilbert. A.D. 1600.

While magnetism was making slow advances by means of insulated observations, it was destined to receive a vigorous impulse from the pen of Dr Gilbert of Colchester. This eminent individual, who was physician in ordinary to Queen Elizabeth, published, in 1600, his *Physiologia Nova, seu Tractatus de Magnete et Corporibus Magneticis*, a work which contains almost all the information concerning magnetism which was known during the two following centuries. It relates chiefly to the natural loadstone, and to artificial magnets, or bars of steel which have acquired similar properties. He applies the term magnetic to all bodies which are acted upon by loadstones and magnets, in the same manner as they act upon each other, and he finds that all such bodies contain iron in some state or other. He considers the phenomena of electricity as having a considerable resemblance to those of magnetism, though he points out the differences by which the two classes of phenomena are marked. In treating of the directive power of the needle, he supposed, "that the earth itself being in all its parts magnetical, and the water not, wherever the land was, there would the needle turn, as to the greater quantity of magnetical matter." He regarded the earth as acting upon a magnetized bar, and upon iron, like a magnet, the directive power of the needle being produced by the action of magnetism of a contrary kind to that which exists at the extremity of the needle directed towards the pole of the globe. He gave the name of *pole* to the extremities of the needle which pointed towards the poles of the earth, conformably to his views of terrestrial magnetism, calling the extremity that pointed towards the N. the *south pole* of the needle, and that which pointed to the S. the *north pole*.

Bond. A.D. 1650.

About the year 1650, Mr Bond, a teacher of mathematics in London, who had been employed to superintend the publication of the popular treatises on navigation, published a work called the *Seaman's Calendar*, in which he maintains that he has discovered the true progress of the deviation of the compass; and in another book, called *The Longitude Found*, and in the *Phil. Trans.* 1668, he published a table of the computed variations for London for many years to come, extending from 1663 to 1716. The results which this table contains agree very nearly with those which were observed for the next twenty-five years, but after that the differences became very great. In a subsequent paper in the *Phil. Trans.* for 1673, Bond attempted to account for the change in the variation and dip of the needle, by *two magnetic poles*, and a magnetic axis inclined to the axis of the earth. He asserted that he knew the period of this revolution, as well as its cause; and he proposed to determine the longitude by means of the dip of the needle. He did not, however, think proper to communicate either his views or method to the public.

Newton, &c.

Newton, Huygens, Hooke, and some of the other philosophers who flourished about the end of the seventeenth century, were occupied, though not to a great degree, with the subject of magnetism. Some of their observations and discoveries are referred to in a manuscript volume of notes and commentaries, written by David Gregory in 1693, in a copy of Newton's *Principia*, and used by Newton in improving the second edition. Newton, who considered the magnetic force as different from that of gravity,[1] had supposed that the law of magnetic action approaches to the inverse triplicate ratio of the distance; but Gregory did not adopt this opinion, and invalidates the arguments which were used in its support. Newton committed another mistake in asserting, as we shall afterwards see, that red hot iron has no magnetic property.

Dr Hooke, A.D. 1684.

Several interesting experiments had been made by Dr Gilbert, on the effects of heat in destroying magnetism, and also in inducing it in substances susceptible of being impregnated. He likewise made numerous experiments with bars of iron and steel placed in the magnetic meridian and exposed to great heats. Dr Hooke took up this subject in 1684. He used rods of iron and steel about seven inches long and one-fifth of an inch in diameter, and he found that they acquired permanent magnetism when strongly heated in the magnetic meridian, and allowed to cool in the same position. The permanency of the effect was greater, and the magnetism stronger, when the rods were suddenly cooled in cold water, so as to give them a very hard temper. He found that the end which was next to the N., or the lower end of a vertical bar, was invariably a permanent N. pole. Even when the upper end alone was quenched, while the rest of the bar cooled slowly, that end became a sensible S. pole. If the same process was adopted when the steel bar lay at right angles to the magnetic meridian, no magnetism was acquired.

Dr Halley. A.D. 1672, 1683.

The subject of terrestrial magnetism now occupied the attention of our eminent countryman, Dr Edmund Halley. He had observed a change in the variation of the needle so early as 1672, a year before he left school; and in 1683, he published[2] his *Theory of Magnetism*, which to a certain extent forms the nucleus of more modern hypotheses. He regarded the earth's magnetism as caused by four poles of attraction, two of them near each pole of the earth; and he supposes "that in those parts of the world which lie nearly adjacent to any one of these magnetic poles, the needle is governed thereby, the nearest pole being always predominant over that more remote." He supposes that the magnetic pole, which was in his time nearest Britain, was situated near the meridian of the Land's End, and not above 7° from the N. pole; the other N. magnetic pole, the strongest, being in the meridian of California, E. Long. 246°, and about 15° from the N. pole of the earth. He placed one of the two S. poles about 16° from the S. pole of the globe, and 95° W. from London; and the other, or the most powerful of the four, about 20° from the S. pole, and 120° E. of London.

Dr Halley's theory.

In order to account for the change in the variation, Dr Halley, some years afterwards, added to these reasonable suppositions the very extraordinary one, that our globe was a hollow shell, and that within it a solid globe revolved, in nearly the same time as the outer one, and about the same centre of gravity, and with a fluid medium between them. To this inner globe he assigned two magnetic poles, and to the outer one other two; and he conceived the change in the variation of the needle to be caused by a want of coincidence in the times of rotation of the inner globe and the external shell. "Now, supposing," says he, "such an external sphere having such a motion, we may solve the two great difficulties in every former hypothesis; for if this exterior shell of earth be a magnet, having its poles at a distance from the poles of diurnal rotation; and if the internal nucleus be likewise a magnet, having its poles in two other places, distant also from its axis, and these latter, by a gradual and slow motion, change their places in respect of the external; we may then give a reasonable account of the four magnetic poles, as also of the changes of the needle's variation." From some reasons which Dr Halley then states, he concludes "that the two poles of the external globe are fixed in the earth, and that if the needle were wholly governed by them, the variation would be always the same, with some little irregularities; but the internal sphere, having such a gradual translation of its poles, influences the needle, and directs it variously, according to the result of the attractive and directive power of each pole, and consequently there must be a period of revolution of this internal ball, after which the variation will return as before."

---

[1] *Principia*, lib. iii., prop. 6.

[2] *Phil. Trans.*, No. 248.

This theory excited so much notice, that an application was made to William and Mary, for a ship, "in order to seek, by observation, the discovery of the rule for the variation of the compass." The command of a ship of the royal navy was in consequence given to Dr Halley; and, in the accomplishment of the object which he had in view, he performed two voyages, one in 1698 and the other in 1699, in which he traversed various parts of the Pacific and Atlantic Oceans, and obtained such a number of valuable results, that he completed and published in 1701 a chart of the variation of the needle, which exhibited to the eye the general law of its phenomena, by means of lines joining those places where the variation was equal.

Graham. A.D. 1722.

Daily variation discovered.

The very important discovery of the daily variation of the needle was made in 1722, by Mr Graham, a celebrated mathematical instrument maker in London. While the needle was advancing by an annual motion to the westward, Mr Graham found that its N. extremity moved westward during the early part of the day, and returned again in the evening to the eastward, to the same position which it occupied in the morning, remaining nearly stationary during the night. Mr Graham at first ascribed these changes to defects in the form of his needles; but, by numerous and careful observations, repeated under every variation of the weather and of the heat and pressure of the atmosphere, he concluded that the daily variation was a regular phenomenon, of which he could not find the cause. It was generally a maximum between ten o'clock A.M. and four o'clock P.M., and a minimum between 6 and 7 o'clock P.M. Between the 6th February and the 12th May 1722, he made a thousand observations in the same place, from which he found that the greatest westerly variation was 14° 45′ and the least 13° 50′; but in general it varied between 14° 35′ and 14°, giving 35′ for the amount of the daily variation.

Law of the magnetic force.

Whiston, Hauksbee, and Brooke Taylor.

The law of the magnetic force, or the rate at which it varies with the distance, had, as we have seen, occupied the attention of Sir Isaac Newton and David Gregory. Numerous experiments were made by various authors for the same purpose, a large collection of which have been published by Scarella, in his treatise *De Magnete*, published at Brescia in 1759. Muschenbroeck[1] made a great number of experiments with the same view; but as the joint action of the four poles was never considered, the precise law of variation remained unknown. Mr Whiston, Mr Hauksbee, and Dr Brooke Taylor employed a much better method, namely, the deviation of a compass-needle from the meridian, produced by the action of a magnet at different distances; and the conclusion which they drew from their experiments was, that the magnetic force was proportional to the sines of half the arcs of deviation, or nearly in the inverse sesqui-duplicate ratio of the distance, or as the square roots of the fifth powers of the distances.[2]

Mr Michell.

Notwithstanding this strange conclusion, the observations to which we have referred were of great value; and Mr Michell[3] succeeded in deducing from them, in 1750, the true law of magnetic action. "There have been," says Mr Michell, "some who have imagined that the decrease of the magnetic attraction and repulsion is inversely as the cubes of the distances; others, as the squares; and others, that it follows no certain ratio at all, but that it is much quicker at great distances than at small ones, and that it is different in different stones. Among the last is Dr Brooke Taylor and Muschenbroeck, who seem to have been pretty accurate in their experiments. The conclusions of these gentlemen were drawn from their experiments, without their being aware of the third property of magnets just mentioned, which, if they had made proper allowances for, together with the increase and diminution of power in the magnets they tried their experiments with, all the irregularities they complained of (as far as appears from their relations of them) might very well be accounted for, *and the whole of their experiments coincide* with the squares of the distances inversely."

Torsion balance.

It is to Mr Michell also that we owe the introduction of the torsion balance, for measuring small forces; an instrument which, as we shall see, was employed with singular success and dexterity by Coulomb in his electrical, magnetical, and hydrodynamical researches: and the science of magnetism is no less indebted to Mr Michell for his invention of the method of double touch, as it is called, by which artificial magnets may be made with greater strength than could have been obtained from the previous method of Duhamel. Dr Gowen Knight, who first taught us to make powerful magnets, accounted for the phenomena of magnetism by supposing that a fluid whose particles repelled each other exists in space and in the pores of steel, and passes in one direction only between magnetic poles. Attraction takes place when the fluid circulates from the S. pole of one magnet to the N. pole of another, and repulsion from its circulation from the N. or S. pole of one magnet to the same pole of the other.[4]

Descartes.

Euler. A.D. 1757.

The hypothesis of Descartes, who explained the polarity of the needle by means of currents moving rapidly from the equator to the poles, was adopted and defended by Euler and Daniel Bernoulli; but we cannot afford any space for such useless speculations. Euler afterwards occupied himself more advantageously for science in attempting to investigate mathematically the direction of the needle on every part of the earth's surface.[5] Perceiving the intricacy which would arise from the adoption of four poles, as imagined by Halley, he tried the effect of employing two poles not diametrically opposite; and he found, that when a proper position was given them, the variation under the same meridian might be both easterly and westerly, as in Halley's chart. The solution which he has given is founded on the principle, "that the magnetic direction on the earth follows always the small circle which passes through the given place, and the two magnetic poles of the earth;" or that the horizontal needle is a tangent to the circle passing through the place of observation, and through the two points on the earth's surface where the dipping needle becomes vertical, or the horizontal needle loses its directive power. In the application of this principle, Euler makes four different suppositions respecting the magnetic poles: 1. That they are diametrically opposite to each other; 2. That they are in opposite meridians, but not in opposite parallels; 3. That they are on the same meridian; and, 4. That they have every other situation whatever. The first of these suppositions he finds to be quite irreconcileable with the observed phenomena, but in the other three he finds that the variation may be both easterly and westerly in the same meridian. By successive approximations he finds the position of the two magnetic poles in 1757 to be as follows:—The N. pole in Lat. 76. N., and Long. 96. W. from Tene-

---

[1] Muschenbroeck's experiments, though valuable in themselves, led to no definite results. They will be found in *Phil. Trans.*, 1725; *Introduction to Natural Philosophy*, 1744; and *Essai de Physique*, 1751.

[2] *Phil. Trans.*, Nos. 368, 396. Dr Brooke Taylor had, in an earlier paper (*Phil. Trans.*, 1721) come to the conclusion that the force was different in different magnets, and decreased quicker at great distances than at small ones, an experimental fact, as shown by Sir W. Harris, *Rudimentary Magnetism*, part iii., 224.

[3] *A Treatise of Artificial Magnets*, 8vo, Lond. 1750, p. 19.

[5] *Berlin Memoirs*, 1757, 1766.

History.

riffe; and the S. pole in Lat. 58. S., and Long. 158. W. from Teneriffe. To this dissertation Euler has added a chart of the curves of equal variation, calculated on the preceding principles, and suited to 1757; and their general accordance with observation is very surprising. In a subsequent dissertation Euler endeavoured to improve his theory, by supposing the two magnetic poles to be at the surface of the earth. The chord joining these poles he calls the magnetic axis, and the middle point of that chord its magnetic centre. Then, if we draw a line from the place of observation to the magnetic centre, and consider this as the base of an isosceles triangle, one of whose sides is the magnetic axis, the other side will be the direction of a freely suspended needle. This hypothesis, though it has various defects, fulfils, as has been remarked, certain conditions that are essential to a good theory. 1. It gives the needle the approximately accurate positions at the equator, the needle and the axis being then parallel. 2. It fulfils the condition of the needle and axis, forming a continuous line at the poles. 3. It furnishes two points at which the needle would be vertical; and 4. It gives a series of positions, single for each place, and having a certain, and oftentimes pretty close, approach to the true position.

A.D. 1766.

Tobias Mayer.

The celebrated Tobias Mayer, in an unpublished memoir, read before the Royal Society of Göttingen, gave an account of a series of experiments on magnetism, from which he concluded that the force was in the inverse ratio of the square of the distance. Experiments made about the same time by Benjamin Martin,[1] indicate a force inversely as the square roots of the cubes of the distances.

Lambert. A.D. 1756.

The law of magnetic action occupied the particular attention of M. Lambert, the celebrated Prussian philosopher, who has published an account of his labours in the *Memoirs of the Academy of Berlin* for 1756. Having placed a mariner's compass at various distances from a magnet, and in the direction of its axis, he observed the declination of the needle produced by the magnet, and the obliquity of the magnet to the needle's axis. From several observations at different obliquities, he found that the action of magnetism on a lever was proportional to the sine of the angle of its obliquity to the axis of the lever or needle. M. Lambert then proceeded to study the effect of distance, and he discovered that the force of a magnet is proportional to the distance of the nearest pole of the magnet from the centre of the needle, diminished by the square of a constant quantity, nearly equal to two-thirds of the length of the needle. This result he found to be true with magnets ten times larger, and needles twice as short; but as the law led him to a strange result, as if the action on a magnet were exerted from a centre beyond itself, he was therefore obliged to take another method of determining the law of action, namely, by a series of experiments on the directive power of the magnet,[2] from which he inferred, "that the force of each transverse element of a magnet is as its distance from the centre, and its action on a particle of another magnet inversely as the square of the distance." By means of this law he calculates the position of a very small needle, and draws three of the curves to which it should be a tangent, and these coincide very accurately with some of those which he had observed.[3]

Dr Robison. A.D. 1769.

Our countryman, Dr Robison, had been pursuing similar inquiries before he had seen Lambert's experiments. He got some magnets made, composed of two balls connected by a slender rod; and after magnetizing them strongly, he found that the force of each pole resided nearly in the centre of the ball. In this way the attractive and the directive powers of the magnets were easily computed; and the result was, that the force of each pole was inversely as the square of the distance. In no case did the error of this hypothesis amount to one-fifteenth of the whole; and in the calculation for the phenomena of the directive power, the errors were still smaller. When Dr Robison had seen Lambert's second memoir, he repeated all his former experiments in Lambert's manner, taking the precaution of keeping the needle in its natural position, which he had not previously attended to; and the results which he now obtained were still more conformable to his conjecture as to the law of variation. Dr Robison tried another method of ascertaining the law of magnetic action. In 1769, or 1770, he constructed a needle of two balls joined by a slender rod; and having touched it with great care, so as to keep the whole strength of the poles near the centre of the balls, he counted the number of oscillations which it performed horizontally in a given time by the force of the earth's magnetism. "He then placed it on the middle of a very fine and large magnet, placed with its poles in the magnetic meridian, the N. pole pointing S. In this situation he counted the vibrations made in a given time. He then raised it up above the centre of a large magnet, till the distance of its poles from those of the great magnet was changed in a certain proportion. In this situation its vibrations were again counted. It was tried in the same way in a third situation, considerably more remote from the great magnet. Then having made the proper reduction of the forces corresponding to the obliquity of their action, the force of the poles of the great magnet was computed from the number of vibrations." The results of these experiments were the most consistent with each other of any that Dr Robison made for determining the law of the magnetic force; and it was chiefly from them that he thought himself authorized to say, with some confidence, that it is inversely as the square of the distance. When Dr Robison, however, observed, some years afterwards, that Æpinus, in 1777, conceived the force to vary inversely as the simple distance, he repeated the experiments with great care, and added another set made with the same magnet, and the same needle placed at one side of the magnet instead of above it. By this arrangement, which greatly simplified the process, the result of the whole was still more satisfactory. The inverse law of the square of the distance was therefore well established.

Theory of Æpinus. A.D. 1759.

Various speculations respecting the cause of the phenomena of magnetism had been hazarded by different authors; but it was reserved for M. Æpinus to devise a rational hypothesis, which embraced and explained almost all the phenomena which had been observed by previous authors. This hypothesis, which he has explained at great length in his *Tentamen Theoriæ Electricitatis et Magnetismi*, published in 1759, may be stated in the following manner:—

1. In all magnetic bodies there exists a substance which may be called the magnetic fluid, whose particles repel each other with a force inversely as the distance.

2. The particles of this fluid attract the particles of iron, and are attracted by them in return with a similar force.

3. The particles of iron repel each other according to the same law.

4. The magnetic fluid moves through the pores of iron and soft steel with very little obstruction; but its motion is more and more obstructed as the steel increases in hardness or temper, and it moves with the greatest difficulty in hard-tempered steel and the ores of iron.

Methods of making artificial magnets.

The method of making artificial magnets, which was practised by the philosophers of the seventeenth century, was a very simple, but a very inefficacious one. It consisted in merely rubbing the steel bar to be magnetized upon one of the poles of a natural or artificial magnet, in a direction at right angles to the line joining the poles of the magnet. Towards the middle of the eighteenth century, however, the art of making artificial magnets had excited general attention.

[3] A popular account of Lambert's researches will be found in Sir William Snow Harris's *Rudimentary Magnetism*, part iii., arts. 191–203.

Marcel, Savery, and Desaguliers had succeeded in making tolerably good artificial magnets; but it is to Dr Gowin Knight, an English physician, that we are indebted for the discovery of the first good method of making powerful magnets. This method he kept secret from the public; but it was afterwards published by Dr Wilson. Duhamel, Canton, Michell, Antheaume, Savery, Æpinus, Robison, Coulomb, Biot, Scoresby, Logeman, and others, made various improvements on this art, which will be described when we arrive at that part of our subject.

Experiments of Canton.
A.D. 1756.

The science of magnetism owes many obligations to Mr John Canton, one of the most active experimental philosophers who adorned the middle of the eighteenth century. In or previous to the year 1756, he made no fewer than 4000 observations on the diurnal variation of the needle, with the view of determining its amount, and investigating its origin. He found the daily change different in different seasons of the year, as shown in the following table:—

January	7′ 8″	July	13′ 14″
February	8 58	August	12 19
March	11 17	September	11 43
April	12 26	October	10 36
May	13 0	November	8 9
June	13 21	December	6 58

He found, also, that the time of minimum westerly variation at London was between eight and nine o'clock A.M., and the time of maximum between one and two o'clock P.M., the needle returning to its morning position about eight or nine in the evening. A series of similar observations were made with nearly the same results by Mr Van Swinden; but this excellent observer discovered, that some time before the hour in the morning when the westerly minimum took place, and after the same hour in the evening, a motion of the needle both to the eastward and westward took place; that is, the morning westerly variation is sometimes preceded by a small easterly variation, and the principal easterly variation in the evening is followed by a small westerly variation.

Van Swinden.

Canton explained the westerly variation of the needle, and the subsequent easterly motion, by supposing that the heat of the sun, acting upon the eastern parts of the earth, weakens their influence, as heat is known to do that of a magnet, and consequently the needle will move to the westward. In the same way, as the sun warms the western side of the earth in the afternoon, the needle will then take a contrary direction.

Discoveries of Coulomb.

One of the ablest cultivators of the science of magnetism was the celebrated Coulomb, who, by the application of the principle of torsion, first used by Michell, determined the correct law of magnetic attractions and repulsions. After measuring with great nicety, by the torsion balance, the force requisite to make a magnetic bar, suspended horizontally, deviate any number of degrees from a given position, he was enabled to verify the discovery of Lambert already mentioned, that the effect of terrestrial magnetism is proportional to the sine of the angle which the magnetic meridian forms with the axis of the magnet upon which it acts. By making the homologous poles of two magnetized wires repel each other, he observed the force of torsion which was necessary to overcome certain quantities of their mutual repulsion, and, at the distances 12°, 17°, and 24°, he found that the repulsive forces were as the numbers 3312, 1692, and 864, deviating little from 3312, 1650, and 828, which they would have been had the repulsive force varied in the inverse ratio of the square of the distance. The excess of 42 and 36 in the experimental numbers was owing to the circumstance that it was not a particle, but a portion of each wire from which the repulsive force emanated; so that the force of the other particles being exerted less obliquely, and, therefore, being stronger at greater distances, ought to produce an excess such as that actually observed. A similar result was obtained when the contrary poles of the magnetized wires were made to attract each other; so that Coulomb concluded that the attractive and repulsive forces exercised by two magnetic particles are inversely as the square of their distances, a result which he confirmed by several other methods than that which we have noticed.

Distribution of magnetism.

Discoveries of Coulomb.

Provided with such a delicate instrument as the torsion balance, Coulomb was enabled to apply it with singular advantage to almost every branch of the science. His first object was to determine the law according to which magnetism is distributed in a magnetic bar. It was of course well known that the magnetism in the middle of the bar was imperceptible, and that it increased according to a regular law, and with great rapidity, towards each of its poles. By suspending a small proof needle with a silk fibre, and causing it to oscillate horizontally opposite different points of a magnetic bar placed vertically, Coulomb computed the part of the effect which was due to terrestrial magnetism, and the part which was due to the action of the bar; and in this way he obtained the following results, which show the extreme rapidity with which magnetism is increased towards the poles.

Distances from the North end of the Bar.	Intensity of the Magnetism at these Distances.

In examining the distribution of electricity in a circular plane, Coulomb found that the thickness of the electric stratum was almost constant from the centre to within a very small distance of the circumference, when it increased all on a sudden with great rapidity. He conceived that a similar distribution of magnetism took place in the transverse section of a magnetic bar; and, by a series of nice experiments with the torsion balance, he found this to be the case, and established the important fact, that the magnetic power resides on the surface of iron bodies, and is entirely independent of their mass.

Effects of temperature.

The effect of temperature on magnets was another subject to which Coulomb directed his powerful mind; but he did not live to give an account of his experiments, which were published after his death by his friend M. Biot. Coulomb found that the magnetism of a bar, magnetized to saturation, diminished greatly by raising its temperature from 12° of Reaumur to 680°; and that when a magnetic bar was tempered at 780°, 860°, and 950°, of Reaumur, the development of its magnetism was gradually increased, being more than double at 900° of what it was at 780°. He found also that the directive force of the bar reached its maximum when it was tempered at a bright cherry-red heat at 900°; and that at higher temperatures the force diminished. It is to Mr Barlow, however, as we shall presently see, that we are indebted for the complete investigation of the influence of temperature on the development of magnetism.

Method of making artificial magnets.

Coulomb made many valuable experiments on the best methods of making artificial magnets, and he subjected all the various processes that had been previously employed to the test of accurate measurement. His experiments on the best forms of magnetic needles are equally valuable; but the most interesting of his researches, and the last to which he devoted his great talents, were those which relate to the action of magnets upon all natural bodies. Hitherto iron, steel, nickel, and cobalt, had been regarded as the only

Universal magnetism.

magnetic bodies; but, in the year 1802, Coulomb announced to the Institute of France, that all bodies whatever are subject to the magnetic influence, even to such a degree as to be capable of accurate measurement. The substances employed by Coulomb were in the form of a cylinder or small bar, about one-third of an inch in length and one-thirtieth in thickness, and they were suspended by a single fibre of silk between the opposite poles of two powerful steel magnets, placed in the same straight line, and having their opposite poles at a distance exceeding by a quarter of an inch the length of the cylinders. The cylinders were then made to oscillate between the poles of the magnets, and were protected from all motions of the air by a glass receiver. The result of these experiments was, that whatever was the substance of the cylinders, they always arranged themselves in a line joining the poles of the magnets, and returned to that position whenever they were deflected from it. These experiments were made with cylinders of gold, silver, copper, lead, tin, glass, wood, chalk, bone, and every variety of substance, organic and inorganic. The only explanation which Coulomb could give of these phenomena was, either that all bodies whatever were susceptible of magnetism, or that they contained small portions of iron or other magnetic metals, which communicated to them the property of obeying the magnet. In order to investigate this subject, MM. Sage and Guyton prepared highly purified needles of the different metals, and M. Coulomb found that the momenta of the forces with which they were solicited by the magnets were as follows:—

Lead	0·00674
Tin	0·00591
Silver	0·00520
Gold	0·00406
Copper	0.00406

the momentum of torsion alone, for all the needles, being 0·00136, a little more than a fourth of the action which the magnets exert upon the needles.

In order to determine if these phenomena were owing to particles of iron disseminated through the bodies, Coulomb fabricated needles out of three different mixtures of white wax and iron filings, and he found that the forces exerted by magnets upon these needles were proportional to the absolute quantities of iron which they contain. Coulomb now tried a needle of silver, purified by cupellation, and another needle of silver alloyed with $\frac{1}{320}$th part of iron, and he found that the action of the magnet upon the former was 415 times less than upon the latter. Hence there will be 415 times less iron in the pure than in the impure silver; and since the latter contains $\frac{1}{320}$th part of its weight of iron, the first will contain $\frac{1}{415}$th of $\frac{1}{320}$th, or $\frac{1}{132,800}$th, or it will contain 132,799 parts of pure silver and one of iron, a quantity of alloy beyond the reach of chemical detection.

The Abbé Haüy, by a process which he calls Double Magnetism, endeavoured to make Coulomb's process more effectual. He deflected a delicately-suspended magnetic needle from the meridian, by a magnetic bar placed so as to make the needle stand E. and W. A very feeble magnetic force was then sufficient to make it turn on its centre of suspension. M. Becquerel having found that a needle of soft iron might be used in place of the magnetic one of Haüy, formed his needles of several oxides of iron, inclosed in a thin paper case, suspended in different positions at a given distance from the pole of a magnetic bar; and he found, what may be considered as the first observed fact in diamagnetism, that the paper-case needles made of an admixture of the second and third oxides of iron, instead of directing themselves to the pole of the magnet like the soft-iron needle, stood at right angles to the line of the poles. Upon repeating Coulomb's experiment with needles of white wood and gum lac, suspended very near the magnets, but above the line of the poles, he found that they took the same position as the paper-case needles.

Humboldt. A.D. 1798-1803.

Amongst the scientific travellers who contributed to our knowledge of terrestrial magnetism, Baron Alexander Humboldt was one of the most distinguished. Himself an accurate and scientific observer, and possessed of nice instruments and methods of observation, he made numerous accurate observations on the dip and variation of the needle in various parts of the earth, and particularly near the magnetic equator; and by means of these valuable data, M. Biot was enabled to throw much light on the subject of terrestrial magnetism. Hitherto the magnetic poles had been considered as either on or very near the surface of the earth; but as it had been found impossible to deduce the phenomena of the variation and dip of the needle, philosophers were led to consider the situation of these poles as indeterminate. M. Biot was the first to adopt this view of the subject; and, after numerous comparisons, he came to the conclusion, that the nearer these poles were placed to each other, the greater was the agreement between the computed and observed results; and by considering the two poles as indefinitely near each other in the centre of the earth, the computed and observed measures approximated as closely as could be expected. Hence it was inferred that the phenomena of terrestrial magnetism were not such as are produced by permanently magnetic bodies, but those rather that arise from simple iron or ferruginous masses, which are only temporarily magnetic. In this manner M. Biot was led to express the law of terrestrial magnetism in a complicated formula, which represented the observations with wonderful accuracy.

M. Biot.

Professor Krafft.

In the year 1809 Professor Krafft of St Petersburg undertook the very same inquiry, and after comparing the same observations which were used by Biot, with the respective situations of the places where they were obtained, he arrived at the following simple law:—"If we suppose a circle circumscribed about the earth, having the two extremities of the magnetic axis for its poles, and if we consider this circle as a magnetic equator, the tangent of the dip of the needle, in any magnetic latitude, will be equal to double the tangent of this latitude." Upon re-examining his former formula, M. Biot found that it was reducible to the above simple law, a coincidence which may be considered as giving it additional confirmation.

Professor Hansteen.

One of the most zealous and successful cultivators of magnetical science is Professor Hansteen of Christiania, who published, in 1817, an able work on the magnetism of the earth.[1] The Royal Society of Denmark proposed, in 1811, the prize question, "Is the supposition of one magnetical axis sufficient to account for the magnetical phenomena of the earth, or are two necessary?" Professor Hansteen's attention had been previously drawn to this subject by seeing a terrestrial globe, on which was drawn an elliptical line round the S. pole, and marked *Regio Polaris magnetica*, one of the foci being called *Regio fortior*, and the other *Regio debilior*. As this figure professed to be drawn by Wilcke, from the observations of Cooke and Furneaux, Hansteen was led to compare it with the facts; and the result of the comparison being favourable, be was induced to study the theory of Halley, which had previously appeared to him wild and extravagant. The result of his researches, however, was favourable to that part of Halley's theory which assumes the existence of four poles and two

[1] *Untersuchungen über den Magnetismus der Erde*, 4to, Christiania, 1817. This work was first made known in England by Sir David Brewster, in two articles in the *Edin. Phil. Journal* for 1820, vol. iii., p. 138, and vol. iv., p. 114; and an account of his subsequent researches, drawn up by Hansteen himself, appeared in the *Edin. Journal of Science* for 1826, vol. v., p. 65.

Hansteen's researches.

magnetic axes. Hansteen's *Memoir*, which was crowned by the Danish Society, forms the groundwork of the larger volume which he published in 1817. In his fifth chapter, on the Mathematical Theory of the Magnet, he deduces the law of magnetic action from a series of experiments similar to those of Hauksbee and Lambert. Assuming that the attraction or repulsion between any two magnetic particles is directly as the intensity of the force, and inversely as some unknown power t of the mutual distance of these particles, and supposing that the magnetic intensity of any particle is proportional to some power r of its distance a from the centre of the magnet, he finds the following expression for the effect F, which a linear magnet would have upon a magnetic point situated anywhere upon the axis produced:—

$$F=\int\frac{x^r\,dx}{(a-x)^t}-\int\frac{x^r\,dx}{(a+x)^t};$$

x being the length of half the axis of the linear magnet, and F (multiplied by a constant quantity, depending on the degrees of magnetism which the point and line possess) representing the force. In conducting the experiments, Hansteen placed a very sensible compass upon a horizontal table, so that the needle pointed to 0°. From beneath the centre of this needle, and perpendicular to its direction, or to the magnetic meridian, he drew a straight line upon the table, and divided it into portions, so that *ten* of them were equal to the half axis a of the artificial magnet. This magnet was then placed on the line at different distances from the needle, and the deviation of the needle from the magnetic meridian which it produced was accurately observed for each distance. Upon comparing the results, and calculating them by the formula, upon the supposition that t was 1 or 3, the differences were very great; but by making $t=2$, the calculated and observed results agreed remarkably well, as the following table shows:—

Values of a, or Distances in half Axes of the Magnet.	Values of F, or increase of the Force.			
	Observed Values.	Calculated Values.		
		$t=2$ $r=1$	$t=2$ $r=2$	$t=2$ $r=3$
11	1·000	1·000	1·000	1·000
10	1·306	1·334	1·334	1·325
9	1·834	1·835	1·836	1·836
7	3·947	3·938	3·945	3·949
5	11·015	11·072	11·119	11·154
4	22·441	22·245	22·411	22·530

On the law of magnetic force.

From this remarkable coincidence between the observed and the computed results, Hansteen concludes that "*the attractive or repulsive force with which two magnetic particles affect each other, is always directly as their intensities, and inversely as the squares of their mutual distance.*" He shows that the undetermined value of r produces almost no effect at considerable distances; and he is inclined to think that $r=2$, or that *the absolute intensity of any magnetic particle, situated in the axis, is proportional to the square of its distance from the middle point of that axis.* Mr Hansteen has also demonstrated that *the distance from the middle of a magnet being the same, the force opposite the poles, or in the direction of the axis, is double of the force in the magnetic equator.* If a globe contains at its centre an infinitely small magnet, Hansteen shows that, *near the magnetic equator, the dip must increase twice as rapidly as the magnetic latitude, and, near the pole, half as rapidly;* and that *the increment of the dip must be equal to the alteration of the latitude of that part of the globe where the dip is* 54° 44′. Our author also states, that if the earth had only one magnetic axis, whose centre coincided with that of the earth, the lines of equal dip would coincide with those of equal intensity; but as this is far from being the case, his opinion that there are two magnetic axes becomes more probable.

Hansteen's researches.

On terrestrial magnetism.

The most valuable part, however, of Professor Hansteen's work is that which relates to the number, position, and revolution of the magnetic poles. Having collected all the observations of value that had been made on the variation of the needle, he proved that there were *four points* of convergence among the lines of variation, viz., a weaker and a stronger point in the vicinity of each pole of the globe. The strongest poles N., S., lie almost diametrically opposite to each other, and the same is true of the weaker poles *n*, *s*. These four poles he found to have a regular motion obliquely, the two northern ones N, *n*, from W. to E., and the two southern ones S, *s*, from E. to W.

Since the publication of his results, Professor Hansteen obtained access to the valuable series of magnetical observations made during the British voyage of discovery to the arctic regions; and, after a diligent comparison of them, he obtained new and more accurate determinations of the positions and periods of revolution of the four magnetic poles, which will be found in our chapter on *Terrestrial Magnetism.*

With the view of discovering the nature of the forces by which the phenomena of terrestrial magnetism are produced, Professor Hansteen resolved to ascertain, at different parts of the earth's surface, the *intensity* of its magnetism, and to determine the form of the lines of equal intensity, or, as he calls them, the *isodynamical magnetic lines.* By means of the same needle intrusted to different philosophers, he had observations on the number of its oscillations in a given time made in every part of Europe; and he afterwards undertook a journey to Siberia to make the observations himself in that interesting magnetical region. From these observations he deduced the law given in our chapter on *Terrestrial Magnetism,* according to which the magnetic intensity varies with the dip of the needle.

Professor Hansteen's journey to Siberia was attended with secondary consequences of great value to science. The attention of the Russian government, and the Academy of Sciences at St Petersburg, was thus called to the subject of magnetism; and, on the recommendation of Baron Humboldt, the emperor liberally agreed to erect magnetic observatories in suitable stations, for determining, every *ten* years, the exact position of the *two lines of the variation,* which pass through his empire.

Diurnal changes.

In determining the intensity of terrestrial magnetism, Professor Hansteen observed that the time of vibration of a horizontal needle varied during the day. Graham had previously suspected a change of this kind, but his methods were not accurate enough to prove it. Hansteen, however, found that the *minimum* intensity took place between ten and eleven A.M., and the *maximum* between four and five P.M. He concluded also that there was an annual variation, the intensity being considerably greater in winter near the perihelion, and in summer near the aphelion; that the greatest *monthly* variation was a maximum when the earth is in its perihelion or aphelion, and a minimum near the equinoxes; and that the greatest daily variation is least in winter and greatest in summer. He found also that the aurora borealis weakened the magnetic force, and that the magnetic intensity is always weakest when the moon crosses the equator.

Influence of height.

In making experiments in the round tower at Copenhagen, Hansteen found that the magnetic intensity increased regularly towards the top, where it was a maximum;[1] and having extended his observations, he obtained the general result, that at the foot of any vertical object the needle oscillates *quicker* at the *north* side of it, and *slower* at the *south* side; whereas at the upper end it oscillates *quicker* at the *south* side, and *slower* at the *north* side. In the aerostatic ascent of MM. Gay-Lussac and Biot, they were unable to detect any change in the intensity of terrestrial magnetism at the height of 4000 metres. Saussure, however, had found that the intensity was considerably less on the Col du Géant than at Chamouni and Geneva, the difference in the levels of these places being, in the one case, 10,000, and in the other, 7800 feet, but his observations contradict his conclusion. M. Kupffer more recently obtained a similar result by observations on Mount Elburz, having found a decrease of intensity in rising 4500 feet above his first station; and he explains the result obtained by MM. Gay-Lussac and Biot, by supposing that an increase of intensity was produced by the diminution of temperature. Mr Henwood, on the other hand, made observations at the surface of Dolcoath mine, at 1320 feet beneath its surface, and on a hill 710 feet above the level of the sea, without being able to detect any difference in the intensity.

---

[1] The height of the tower is 126 feet.

To the late Captain Foster[1] we owe many valuable observations on the magnetic intensity made at Spitzbergen and elsewhere. From these he concluded, that the diurnal change in the horizontal intensity is principally, if not wholly, owing to a small change in the amount of the dip. The maximum took place at about 3h 30m A.M., and the minimum at 2h 47m P.M., its greatest change amounting to one eighty-third of its mean value. Captain Foster is of opinion that these changes have the sun for their primary agent, and that his action is such as to produce a constant inflexion of the pole towards the sun during the 24 hours, an idea which Mr Christie had previously stated.[2]

Mr Barlow's discoveries.

About the year 1817, Professor Barlow of Woolwich turned his attention to the subject of magnetism, with the view principally of calculating the effect of a ship's guns on the compass. In trying the effects of different iron balls, he was led to the curious facts, that there exists round every globe and mass of iron a great circle inclined to the horizon at an angle equal to the complement of the dip of the needle; that the plane of this circle is a plane of no attraction upon a needle whose centre is in that plane; that if we regard this circle as the magnetic equator, the tangent of the deviation of the needle from its N. or S. pole will be proportional to the rectangle of the sine of the double latitude, and cosine of the longitude; that when the distance of the needle is variable, the tangent of deviation will be reciprocally proportional to the cube of the distance; and that, all things else being the same, the tangents of deviation will be proportional to the cubes of the diameters of the balls or shells, whatever be their masses, provided their thickness exceed a certain quantity.

These results were published in the first edition of Mr Barlow's *Essay on Magnetic Attractions;* but in the second edition of that work, he has published some curious results respecting the relative magnetic power of different descriptions of iron and steel, and on the effect of temperature on the quality and quantity of the attractive power of iron. The results of the first of these series of experiments were as follow, the numbers expressing the proportional magnetic power of the different descriptions of iron and steel:—

Malleable iron	100	Shear steel, hard	53
Blistered steel, soft	67	Cast iron	48
Blistered steel, hard	53	Cast steel, soft	74
Shear steel, soft	66	Cast steel, hard	49

In his experiments on the effects of temperature, Mr Barlow found that every kind of iron and steel possessed a greater capacity for the development of its magnetism when softened by heat than when cold; from which he concludes that its complete development when cold is prevented only by the hardness or resisting power of the metal. At a *white* heat he found that iron lost entirely its magnetic power, a result apparently inconsistent with the preceding conclusion; but, what was a still more extraordinary circumstance, when the *white* heat, at which there was no magnetism, began to subside into a *bright red*, or *red* heat, an *attractive* power showed itself the *reverse* of what it had when cold; and after it had passed through these two shades of colour, it resumed the same attractive power which it had when cold, the passage from the negative attraction of red passing into the positive attraction of the cold metal at the point of a red heat, the maximum, however, taking place at a blood-red heat.

Mr C. Bonnycastle.

The experimental laws of attraction of an iron shell or sphere, obtained by Mr Barlow, were first examined theoretically by Mr Charles Bonnycastle, who deduced them mathematically from the theory of Æpinus, which supposes the two magnetic fluids to be accumulated in the poles of magnets. This theory, however, led to some improbable consequences, and therefore Mr Barlow was induced to adopt that of Coulomb, with the modification, *that the magnetic power all resides on the surface of iron bodies; and is independent of the mass;* a modification which enabled Mr Barlow to obtain a general analytical expression of the disturbing power of an iron ball at its surface, as compared with that of the earth, and from which he deduced theoretically all his experimental laws.

Barlow's correcting plate.

These important discoveries enabled Mr Barlow to invent a most ingenious method of correcting the error of the compass, arising from the attraction of all the iron on board ships. This source of error had been noticed by Mr Wales, by Mr Downie in 1794, and by Captain Flinders; but it is to Mr Bain[3] that we owe the distinct establishment and explanation of this source of error. As a hollow shell of iron about four pounds in weight acts as powerfully at the same distance as a solid iron ball of 200 pounds weight, Mr Barlow happily conceived that a plate of five or six pounds weight might be made to represent and counteract the amount of the attraction of all the iron on board a vessel, and therefore leave the needle as free to obey the action of terrestrial magnetism as if there were no iron in the ship at all. After this ingenious contrivance had been submitted to the Admiralty, it was tried in every part of the world; and even in the regions which surround the magnetic pole, where the compass becomes useless, it never failed to indicate the true magnetic direction when the correcting plate was properly applied. At Port Bowen, where the dip is 88°, and the magnetic intensity which acts upon a horizontal needle extremely weak, the azimuth compass on board Captain Parry's ship gave the very same variation as that observed on shore. "Such an invention as this," says Captain Parry, "so sound in principle, so easy of application, and so universally beneficial in practice, needs no testimony of mine to establish its merits; but when I consider the many anxious days and sleepless nights which the uselessness of the compass in these seas had formerly occasioned me, I really should have esteemed it a kind of personal ingratitude to Mr Barlow, as well as great injustice to so memorable a discovery, not to have stated my opinion of its merits, under circumstances so well calculated to put them to a satisfactory trial." For this beautiful invention, the Board of Longitude conferred upon Mr Barlow the highest reward of L.500; and the Emperor of Russia, who was never inattentive to the interests of science, sent him a fine gold watch and a rich dress chain.

Magnetism of rotation.

A series of beautiful discoveries was made about this

Mr Christie.

time by M. Arago, Mr Christie, and Mr Barlow, on the influence of rotation on bodies both magnetic and non-magnetic. Mr Barlow, so early as 1818 or 1819, had found, that when a plate of iron was made to turn upon its centre, different parts of its circumference had different degrees of magnetic action on the compass; but here there was no effect discovered as due to rotation. In 1821, Mr Christie, in a series of experiments on iron plates, not only found that different parts in the circumference of the same plate had different attractive powers; but *that the same part had a different influence according as the same plate was made to revolve to the right or left hand.* Mr Christie therefore discovered that there was a *deviation due to rotation*, and that magnetical effects were produced which were nearly independent of the velocity of rotation, and which continued after the rotation had ceased. When the rotation was very rapid, the forces exerted upon the needle were always in the same direction as the forces derived from the slowest rotation, and which continue to act after the rotation has ceased, the former being to the latter nearly as three to two. From all the observations made by Mr Christie, he considers that the direction of the magnetic polarity acquired by rotation, whether at right angles to the line of the dip or not, has always a reference to the direction of the terrestrial magnetic force; and he infers that this magnetism is communicated to it from the earth. "It does not therefore appear from this," says Mr Christie, "that a body can become polarized by rotation alone, independently of the action of another body; so that, if from these experiments we might be led to attribute the magnetic polarity of the earth to its rotation, we must at the same time suppose a source from which magnetic influence is derived. Is it not, then, possible that the sun may be the centre of such influence, as well as the source of light and heat, and that, by their rotation, the earth and other planets may receive polarity from it?" When these experiments were repeated at Port Bowen, in 1825, by Captain Foster, the phenomena were exhibited on a more striking scale.

Mr Barlow.

In December 1824 Mr Barlow began a series of experiments, with the view of ascertaining whether magnetism, as produced by various processes with iron, could be excited or disturbed by rapid rotation. They were completed in January, but their publication was delayed till June, that an account of them might appear along with those of Mr Christie above mentioned. Mr Barlow's first experiments were made on a 13-inch shell attached to a lathe turned by a steam-engine, the mean speed of which was about 640 revolutions in a minute. The deviation of a needle exposed to its action increased with the velocity, and remained constant while the velocity continued constant, the needle always returning exactly to its original position the moment the motion of the ball ceased. This, therefore, is a phenomenon different from that observed by Mr Christie; a temporary effect wholly dependent on the velocity of rotation, whereas that observed by Mr Christie was permanent, and nearly independent of the number of revolutions. In examining the direction of the new force impressed upon the iron shell, he found it to be in every case equivalent to a polarization at right angles to the axis of rotation.

Discoveries of M. Arago.

Previous to the publication of these experiments, and without any knowledge of them, M. Arago had made the remarkable discovery, that if plates of copper and other substances are put into rapid rotation beneath a magnetized horizontal needle freely suspended, the rotatory plate will first cause the needle to deviate from its true direction; and by increasing the velocity, the deviation will increase, till the needle passes the opposite point, when it will continue to revolve, and at last with such velocity that the eye is unable to distinguish it.

M. Arago was led to this beautiful discovery by a previous series of experiments of great interest. He found that a magnetic needle oscillating above or near any body whatever, such as a plate of metal or a surface of water, gradually oscillated in arcs of less and less amplitude, as if it had been placed in a resisting medium; and, what was particularly remarkable, the number of oscillations performed in a given time was not changed. This curious fact was announced to the Academy of Sciences in Paris on the 22d of November 1824; and he was hence conducted to the still more remarkable discovery of the effects of rotation which we have already mentioned.

M. Seebeck.

M. Seebeck of Berlin repeated the experiments of M. Arago on the influence of plates of metal and other substances in diminishing the amplitude of oscillation; but we must reserve our account of them till we come to the chapter on that subject.

Mr Babbage and Sir John Herschel.

The experiments of M. Arago on the rotation of metallic plates were described and repeated by M. Gay-Lussac in London, in the month of March or April 1825; and they excited so much attention, from their connection with the effects observed by Mr Barlow, that Mr Babbage and Sir John Herschel immediately erected an apparatus for repeating them. In their first trial, the deviation of the needle did not exceed 10° or 11° with a revolving plate of copper. In order to enlarge the visible effect, they reversed the experiment, in order to try whether discs of copper and other non-magnetic substances might not be set in motion if suspended over a revolving magnet. A horse-shoe magnet, capable of lifting twenty pounds, was made to revolve rapidly about its axis of symmetry placed vertically. A circular disc of copper, six inches in diameter and one twenty-fifth of an inch thick, was suspended centrally over it, by a silk thread just capable of supporting it. A sheet of paper being interposed and the magnet set in motion, the copper began revolving in the same direction, at first slowly, but with an accelerating velocity. On reversing the motion of the magnet, the velocity of the copper was destroyed gradually. It stopped for an instant, and then immediately began to revolve in the opposite direction. Screens of paper, glass, wood, copper, tin, zinc, lead, bismuth, were interposed betwixt the magnet and the copper but they exerted no sensible interceptive power. But when tinned iron plate was interposed, the magnetic influence was greatly diminished by one plate, and almost annihilated by two thicknesses of it. A piece of iron connecting the two poles of the revolving magnet produced the same effect. The substances in which signs of magnetism were developed by the revolving magnet were—copper, zinc, silver, tin, lead, antimony, mercury, gold, bismuth, and carbon in the state in which it is precipitated from carburetted hydrogen in gas-works. By getting plates of different metals cast in the same mould, they found that the proportional intensity of magnetic action for each respectively was as follows:—

Zinc	1·11	Lead	0·25
Copper	1·00	Antimony	0·01
Tin	0.51	Bismuth	inappreciable.

M. Arago had observed the very remarkable fact, that if the disc of copper be cut from the circumference towards the centre, like radii, but without taking away the metal, the action upon the needle is greatly diminished. After verifying this result, Messrs Babbage and Herschel ascertained that re-establishing the metallic contact with other metals, restored, either wholly or very nearly, the original power of the plate, even though the soldering metal had a very feeble magnetic power. The law of the force, with a decrease of distance, they found to vary between the square and the cube. "The rationale," they say, "of these phenomena, as well as of those observed by Mr Barlow in the rotation of iron, which form only a particular case (though

History.

certainly the most prominent of any) of the class in question, seems to depend on a principle which, whether it has or has not been before entertained, or distinctly stated in words, it may be as well, once for all, to assume here, as a *postulatum*, viz., that *in the induction of magnetism, time enters as an essential element, and that no finite degree of magnetic polarity can be communicated to or taken from any body whatever, susceptible of magnetism, in an instant.*"

The preceding results were verified by Mr Christie, who found, that when a thick plate of copper revolved under a small magnet, the force which deflected the needle varied inversely as the fourth power of the distance; but when the copper discs were small, and the magnets large, the power of the distance was between the square and the cube; when the plates were of different weights, the force was nearly in the ratio of the weights at small distances, but at smaller distances it varied in a higher ratio.

Connection between the magnetic poles and those of maximum cold.

The discovery of two poles of maximum cold on opposite sides of the N. pole of the earth, which was announced by Sir David Brewster in 1820, led him and other authors to the opinion that there might be some connection between the magnetic poles and those of maximum cold. "Imperfect," says he, "as the analogy is between the isothermal and magnetic centres, it is yet too important to be passed over without notice. Their local coincidence is sufficiently remarkable, and it would be to overstep the limits of philosophical caution to maintain that they have no other connection but that of accidental locality; and if we had as many measures of the mean temperature as we have of the variation of the needle, we might determine whether the isothermal poles were fixed or moveable." And he concludes his paper on the mean temperature of the globe with the following paragraph:—"Having thus endeavoured to establish a new law of the distribution of heat over the surface of the globe, it might be no uninteresting inquiry to investigate the causes which have modified in so remarkable a manner the influence of the solar rays. The subject, however, is too comprehensive and too hypothetical to be discussed at present. How far the general form and position of the continents and seas of the northern hemisphere may disturb the natural parallelism of the isothermal lines to the equator—to what extent the current through Behring's Strait, transporting the waters of warmer climates across the polar seas, may produce a warm meridian in the direction of its motion, and throw the coldest parts of the globe to a distance from the pole—whether or not the magnetic, or galvanic, or chemical poles of the globe (as the important discoveries of Oersted entitle us to call them), may have their operations accompanied with the production of cold, one of the most ordinary effects of chemical action—or whether the great metallic mass which crosses the globe, and on which its magnetic phenomena have been supposed to depend, may not occasion a greater radiation of heat in those points where it developes its magnetic influence—are a few points which we may attempt to discuss when the progress of science has accumulated a greater number of facts, and made us better acquainted with the superficial condition as well as the internal organization of the globe."[1]

The two poles of maximum cold, which will likely perform an important part in the future history of terrestrial magnetism, are situate, according to Sir David Brewster, as follows, according to the best observations made both near them and at a distance:—The American pole is situate in N. Lat. 73., and W. Long. 100. from Greenwich, a little to the E. of Cape Walker; and the Asiatic pole in N. Lat. 73., and E. Long. 80., between Siberia and Cape Matzol, on the Gulf of Oby. Hence, the two warm meridians will be in W. Long. 10., and E. Long. 170., the latter passing through Lord Mulgrave's range, and the former between St Helena and Ascension Island. The two cold meridians, or those which pass through the poles of maximum cold, will be in W. Long. 100., and E. Long. 80., the latter passing near Mexico and through Bathurst Island, and the former through Colombo in Ceylon, Berar in Hindustan, and crossing the Oby a little to the W. of Narym in Siberia. The following is the formula which the same author has given for the mean temperature at any point of the globe, T being the mean temperature required, t the maximum equatorial temperature, τ the minimum temperature at each of the cold poles, and δ, δ' the distances of the place from the two cold poles:—

History.

$$T=(t-\tau)\,(\sin.^n\delta\,.\,\sin.^n\delta')+\tau.$$

The distances δ, δ' are found from the formulæ—

$$\cos.\,\delta=\frac{\cos.\,L\,(\cos.\,L-\theta)}{\cos.\,\theta}\text{ and}$$

$$\text{tang. }\theta=\cos.\,M\text{ tang. }L\,;$$

in which L is the co-latitude of the pole of maximum cold, l the co-latitude of the place, and M the difference of longitude between the place and the pole of maximum cold. The values of t and τ have been determined with considerable accuracy, t being nearly 82°·8 Fahrenheit, and τ from 0° to $-3\frac{1}{2}$°. The exponent n is nearly $\frac{5}{8}$ths, but future observations may induce us to increase or diminish it.

Now, it is a remarkable circumstance that the same formula, *mutatis mutandis*, expresses the approximate magnetic intensity of magnetism at any point of the earth's surface, the intensity at the two magnetic poles being supposed equal. If we call S the maximum number of seconds in which any number n of oscillations are performed which takes place at the Island of St Thomas, on the W. coast of Africa, and s the minimum number of seconds in which n oscillations are performed, which takes place at the magnetic poles, then the intensity I will be

$$I=(S-s)\,(\sin.^n\delta\,\sin.^n\delta')+s,$$

δ and δ' being determined by the formulæ already given; adopting the position of the poles in the preceding page. The values of S and s, according to General Sabine and Hansteen, will be about 370″ and 262½″. This formula will give for the *isodynamical lines* a series of returning curves of the nature of Lemniscates, almost similar to those drawn by General Sabine, as given in a future figure, and exactly like the polar isothermal lines.

Connection between the temperature and magnetism of the globe.

The connection thus indicated between the heat and the magnetism of the earth has been studied by succeeding authors, and the general principle has been adopted by many distinguished philosophers. Dr Traill expressed the opinion, "that the disturbance of the equilibrium of the temperature of our planet by the continual action of the sun's rays on its intertropical regions, and by the polar ices, must convert the earth *into a vast thermo-magnetic apparatus*;" and "that the disturbance of the equilibrium of temperature, even in stony strata, may elicit some degree of magnetism." Mr Christie thinks it "not improbable that difference of temperature may be the primary cause of the polarity of the earth, though its influence may be modified by other circumstances." M. Ampère, who ascribes magnetism to transverse electrical currents, thinks that the strata of our globe may form considerable galvanic arrangements, and that the electric currents may be affected by the rotation of the earth. M. Oersted remarks, in his treatise on thermo-electricity,[2] "that the most efficacious excitation of electricity upon the earth appears to be produced by the sun producing daily evaporation, de-oxidation, and heat, all of which excite electrical currents." After stating that the sun daily produces electric currents, and these currents magnetism, he observes, that "thus the earth seems to have a *constant magnetic polarity*, produced in the course of time by the electrical currents which surround it, and a *variable magnetism* produced immediately by the same current." As the sun produces different effects on water and solid bodies, Oersted supposes that the intensity will vary in the same parallel, and the direction of the needle will be oblique to the equator, in consequence of the lines of equal electro-magnetic intensity being twice bent by the influence of the two great masses of continent. "The yearly and daily change," he observes, "must occasion yearly and daily variations. As to the variations comprehended in greater periods, we might perhaps attribute them to a *motion of the coolest points in such continents*, which, it appears, cannot remain the same for ever, because the currents of warmer air must principally be directed to such points." Analogous views have been propounded by M. Kupffer, in a memoir read in 1829 to the Russian Academy, in which he adopts explicitly Sir David Brewster's opinions of the existence of two cold poles distant from the pole of revolution. "But this distribution of temperature," says he, "*appears also to have a great influence on the distribution of the intensity of terrestrial magnetism.* This would no doubt be the case if it is true, as I have tried to show in another memoir, that terrestrial magnetism resides at the surface of the globe. We have here the choice between *two* hypotheses; either the earth should be considered as a magnet existing by itself, and then the intensity of its magnetism will be the inverse of its temperature; or it receives its influence from without, and is only like a piece of soft iron, to which the presence of a distant body communicates magnetism, and then the intensity of its magnetism will increase with its temperature. Though the first of these hypotheses has been hitherto generally adopted, yet the second acquires some probability from the discovery of the magnetic influence of the solar rays, and of the known relation between the diurnal variations of the declination of the needle and the course of the sun." The connection between the poles of maximum cold and those to which the isodynamical magnetic lines are related, is considered by Dr Dalton as a probable supposition. "If the idea," says he, "suggested by Sir David Brewster, in the *Transactions of the Royal Society of Edinburgh*, vol. ix., 1821, be correct (and there seems great reason to believe it to be so), namely, *that there are two poles of greatest cold in the northern hemisphere*, the above observation will enable us to see the natural cause of this remarkable fact. The lands within the arctic circle, in the absence of the sun, must depend upon the S.W. winds from the two great oceans for their winter heat. Those parts of the eastern and western continents which are most remote from the ocean, as measured along the curvilinear tracts of the current of air, must receive that air, in great measure, deprived both of its vapour and its temperature. Accordingly, it is found that the temperature of the N.E. parts of such continents exhibits the extreme of cold. Probably a latitude of 75° N., and a longitude of 90° E. and 90° W., would be found nearly equally cold, and to exceed any other place on the surface of the globe in this respect; and it would be a curious coincidence if Professor Hansteen's two supposed northern magnetic poles should be found in the same positions as the two poles of extreme cold."[1]

Magnetism of the solar rays.

Dr Morichini.

Dr Carpi.

Mrs Somerville.

In a general history of magnetical discoveries, it may be proper to take some notice of the very curious experiments which have been made respecting the influence of the solar rays in the production of permanent magnetism, although, according to the generally received opinion, the existence of such an influence has not been established; but if the propriety of doing this had been doubtful, the observation made by M. Kupffer, as connecting this supposed property of violet light with terrestrial magnetism, would have removed the doubt. Dr Morichini, an eminent physician in Rome, was the first who announced it as an experimental fact, that an unmagnetized needle could be rendered magnetic by the action of the violet rays of the sun. His experiments were successfully repeated by Dr Carpi at Rome, and the Marquis Ridolfi at Florence; but M. d'Hombre Firmas, at Alais, in France, Professor Configliachi of Pavia, and M. Bérard of Montpelier, failed in obtaining decided magnetic effects from the violet rays. In 1814 Dr Morichini exhibited the actual experiment to Sir Humphry Davy, and in 1817 Dr Carpi showed it to Professor Playfair. A few months after Sir Humphry Davy witnessed the experiment, the writer of this article met him at Geneva, and learned from him the fact, that he had paid the most diligent attention to one of Morichini's experiments, and that he saw with his own eyes an unmagnetized needle rendered magnetic by violet light. The following account of the experiment made by Dr Carpi was given to us verbally by Professor Playfair, who approved of the statement of it which we drew up at the time:—"The violet light was obtained in the usual manner, by means of a common prism, and was collected into a focus by a lens of a sufficient size. The needle was made of soft wire, and was found upon trial to possess neither polarity nor any power of attracting iron filings. It was fixed horizontally upon a support, by means of wax, and in such a direction as to cut the magnetic meridian at right angles. The focus of violet rays was carried slowly along the needle, proceeding from the centre towards one of the extremities, care being taken never to go back in the same direction, and never to touch the other half of the needle. At the end of half an hour after the needle was exposed to the action of the violet rays, it was carefully examined, and it had acquired neither polarity nor any force of attraction; but after continuing the operation twenty-five minutes longer, when it was taken off and placed on its pivot, it traversed with great alacrity, and settled in the direction of the magnetical meridian, with the end over which the rays had passed turned towards the N. It also attracted and suspended a fringe of iron filings. The extremity of the needle that was exposed to the action of the violet rays repelled the N. pole of a compass-needle. This effect was so distinctly marked as to leave no doubt in the minds of any who were present, that the needle had received its magnetism from the action of the violet rays." In this state of the subject, Mrs Somerville made some simple and well-conducted experiments, which seemed to set the question at rest, from the distinct and decided character of the results. A sewing-needle an inch long, and devoid of magnetism, had one half of it covered with paper, and the other exposed to the violet rays of the spectrum five feet distant from the prism. In two hours it acquired magnetism, the exposed end exhibiting N. polarity. The *indigo* rays produced an equal effect, and the *blue* and *green* the same in a less degree. The *yellow*, *orange*, and *red* rays had no effect even after three days' exposure to their action. Pieces of blue watch-springs received a higher magnetism. When the sun's light fell upon the exposed end through blue-coloured glass, or through *blue* or *green* riband, the same magnetic effects were produced.

Mr Christie.

The experiments of Mr Christie, an account of which was read to the Royal Society a short time before Mrs Somerville's, confirmed her results to a certain degree, by a different mode of observation. He found that the compound solar rays possessed magnetic influence, and exhibited it in their effect of diminishing the vibrations of magnetized and unmagnetized steel needles, and also needles of copper or of glass, by making them oscillate in the sun's white rays. Mr Christie, however, has remarked, that, as his experiments have not succeeded on repetition

---

[1] *Meteorological Observations and Essays*, second edition, 1834, p. 215.

Zantedeschi.

Baumgartner.

Barlocci.

by Sir William Snow Harris, when made in a vacuum, his results must have been owing to currents of air. In justice to Mr Christie, however, we must mention that Professor Zantedeschi repeated Mr Christie's experiments at Pavia under an Italian sun, with a needle a Paris foot long, and obtained a striking result. This needle, when drawn from its position of equilibrium, through an area of 90°, performed four oscillations in 30^s, the last of which had a semiamplitude of 70^s. In the solar rays it performed in 30^s four oscillations, the last of which had only a semiamplitude of 60°. When he exposed to the sun the N. pole, the semiamplitude of the last oscillation was 6° less than that of the first; while by exposing the S. pole this last oscillation became greater than the first. The experiments of Baumgartner and Barlocci tended to confirm these results. The former found that iron wires polished on a part of their length are magnetized by white solar light, exhibiting a N. pole on the polished part; and the latter has shown that an armed natural loadstone, which carried 1$\frac{1}{2}$ Roman pound, exhibited, after three hours' exposure to the strong light of the sun, an increase of energy equivalent to 2 ounces, or $\frac{1}{8}$th of a pound; while another larger one, which carried 5 pounds 5 ounces, had its strength nearly doubled by two days' exposure. Zantedeschi tried an artificial horse-shoe loadstone, which carried 13$\frac{1}{2}$ ounces; after three days' exposure to the sun it carried 3$\frac{1}{2}$ ounces more, and by continuing its exposure its power increased to 31 ounces. An oxidated magnet gained most power, and a polished one none. He found also that the N. pole of a loadstone exposed to the sun's rays concentrated by a lens acquires strength, while its S. pole, similarly exposed, loses it.

Ries and Moser.

Notwithstanding all these results, the general opinion seems now to be, that light does not exercise any decided effect in producing magnetism. The experiments of MM. P. Ries and Moser were made with needles both polished and oxidated, and also with wires half polished; and polarized as well as common light was made to fall upon them in a concentrated state, but no decided effect upon their number of oscillations could be observed; and they state that they think themselves justly entitled *to reject totally a discovery which, for seventeen years, has at different times disturbed science.*

Sir William Snow Harris. A.D. 1827.

In 1827 Sir William Snow Harris communicated to the Royal Society of Edinburgh his *Experimental Inquiries concerning the Laws of Magnetic Forces*, made with a beautiful and accurate instrumental apparatus, invented by the author for examining the phenomena of induced magnetism. With this apparatus he found that the magnetic development in masses of iron by induction is, *cæteris paribus, directly proportional to the power of the inductive force, and inversely as the distance;* and that the forces which magnets develop in a mass of iron at a given distance, within certain limits, may be taken as a fair measure of their respective intensities. From another series of experiments he has shown that the absolute force of attraction exerted between a magnet and a piece of iron varies with the power of the magnet, and consequently with the force induced in the iron, *cæteris paribus;* and that when the force induced in the iron is a constant quantity, while its distance from a temporary or permanent magnet is variable, *the absolute force varies with the distance.* This result was not only apparent when the magnetic force was varied by induction, but was also satisfactorily shown when varied by magnets of which the relative powers of induction were previously ascertained. Sir W. S. Harris made a number of nice experiments on the absolute force of attraction and repulsion between two magnetized bodies, which he found to be in the inverse ratio of the square of the distance. When, in the case of attraction, the magnets, however, were nearly approximated in relation to their respective intensities, the increments in the forces began to decline, and in some instances at near approximations the absolute force was in the simple inverse ratio of the distance. In the experiments with the repelling poles, the deviations from the regular force were still more considerable, and what is curious in this case, the force became less and less, until the polarity of the weaker magnet appeared to be so counteracted by induction, *that the repulsion was at length superseded by attraction.* Sir W. S. Harris next proceeded to determine the law according to which the forces are developed in different points of the longitudinal magnetic axis between the centre and poles of a magnet, and he found that it varied directly as the square of the distance from the magnetic centre; a law which is uniform in bars of steel regularly hardened and magnetized throughout. This law of distribution is exactly the same as that which has been given by Hansteen.

It is not necessary to mention here the numerous and valuable results obtained by Sir W. S. Harris in his more recent investigations; but there is one so new and interesting as to require special notice. We have already seen that Newton, Brook Taylor, and others, have obtained contradictory results respecting the law of magnetic force. Newton found the force to vary inversely as the cubes of the distance, and was therefore asserted by M. Biot[1] to have had very inaccurate ideas of magnetic phenomena. This criticism is founded on the common notion that magnetism is, like gravity, a central force; whereas Sir W. S. Harris has shown that the law of force given by Newton and others is deducible from their experiments, and that the assertion of Brook Taylor, "that magnetic attraction, as commonly observed, decreases quicker at greater distances than at smaller ones, and is different for different magnets," is not only true as an experimental fact, "but is the necessary result of the elementary laws of magnetism."[2]

Sir W. S. Harris has also published other two memoirs in the *Philosophical Transactions* for 1831, the first *On the Influence of Screens in arresting the progress of Magnetic Action*, and the second *On the Power of Masses of Iron to control the Attractive Force of a Magnet*, of both of which some account will be found in a subsequent section. In a later paper, *On the Investigation of Magnetic Intensity by the Oscillations of the Magnetic Needle*, he exposed an oscillating magnetic bar to a bright sunshine; and though he observed the effect observed by Mr Christie, which that philosopher ascribed to the influence of the sun's rays, yet he found that they all disappeared when the needle was made to oscillate in an exhausted receiver.

M. Haldat. A.D. 1830.

M. Haldat of Nancy communicated, in 1830, to the society of that city, the results of some interesting researches on the incoercibility of the magnetic fluid, or its power of exerting its influence through all bodies, even the most dense; a property which is not possessed by light, heat, or electricity. In this research he adopted various methods of observation, and interposed a great variety of substances; and from the numerous experiments which he made, he has drawn the following conclusions:—1. That the agent or fluid by which the magnetic phenomena are explained is incoercible in the present state of the science; 2. That iron, considered as presenting an exception to this law, coerces the magnetic influences only by acquiring itself the magnetic state; 3. That incandescence does not give to bodies the power of coercing the magnetic influence. In a previous memoir, M. Haldat had obtained some interesting results on the production of magnetism by friction. He found that all hard bodies may, by means of friction, assist in the decomposition of the magnetic fluid, if their action is promoted by the combined action of magnets which, by themselves, are incapable of producing it. If a piece of soft wire, for example, four inches long, and 1-25th of an inch in diameter, be placed horizontally between two bar-magnets with their opposite poles facing each other, and at such a distance that the wire cannot be magnetized, it will receive distinct magnetism by friction with all hard bodies, such as copper, brass, zinc, glass, hard woods, &c. M. Haldat employed the ingenious process of M. Gay-Lussac, of magnetizing soft iron by torsion, in neutralizing the wires before they were magnetized. If they are twisted after receiving magnetism, they will preserve the magnetism which they had received before torsion; but if, after being twisted, they are twisted in an opposite direction, they will become perfectly neutral.

---

[1] *Edinburgh Encyclopædia*, vol. xiii., p. 270.

[2] *Rudimentary Magnetism*, part iii., p. 54.

M. Haldat likewise made some interesting experiments on the effect of the coercive force in steel on the magnetism produced by rotation, and he found that the force with which a revolving steel disc dragged round a magnetic needle was in the inverse ratio of the coercive force of the steel. When the discs were not hot, they had the same effect as those at the ordinary temperature. We owe also to M. Haldat an interesting paper on magnetic figures. Figures of any kind, when traced by the pole of a magnet on a plate of steel, are rendered visible by sifting upon the invisible tracings filings of steel, which arrange themselves in the most beautiful manner along the outlines of the figure which has been traced.

M. Quetelet.
A.D. 1830.

A series of very interesting experiments were published by M. Quetelet of Brussels, *On the successive degrees of Magnetic Force which a Steel Needle receives during the multiple frictions which are employed to magnetize it.* These experiments were made principally before 1830, but they were not given to the public till 1833. The following are the general results which were obtained by the author:—

1. When a needle or bar that had never been magnetized, is magnetized to saturation by the method of separate contact, the magnetic force acquired is a maximum in relation to the forces which can be given to the same needle or bar by the subsequent reversals of its poles.

2. The magnetic force which a needle can acquire becomes weaker in proportion as the reversal of its poles has been multiplied. The series of frictions which tend to bring back the poles to their primitive state are more efficacious than the others.

3. This difference between the forces which the needle acquires after the successive reversals of its poles, goes on continually diminishing, and converges towards a limit. It depends in general on the size of the needle in relation to that of the rubbing bars, as well as in its force of coercion.

4. A needle cannot receive all the magnetic force which it can acquire, if the frictions do not take place over all its surface; this becomes particularly sensible in the reversal of the poles.

5. The rubbing bars give (*cæteris paribus*) to bars of the same dimensions as themselves a magnetic force equal to that which they possess, and in bars of different dimensions the forces acquired are as the cubes of their homologous dimensions. The last part of this proposition was long ago established by Coulomb.

6. When we rub magnetic bars with other bars weaker than themselves, the force of the first diminishes in place of increasing; and it appears that the force becomes that which those latter bars would be capable of giving at the first by directly magnetizing them.

7. The relation which exists between the forces which a needle or a bar receives by successive frictions and the number of these frictions, may be expressed by an exponential formula of three constants.

One of these constants appears to change its value with the size of the bars which are magnetized, at least while these bars have a magnitude which does not exceed that of the rubbing bars, and while they are of the same quality of steel.

In this way we know beforehand the successive degrees of force which a bar takes at each friction, if we have previously determined the law of these augmentations for the same rubbing bars, and for any other bar which we get to serve as the modulus. If the bar which is rubbed has begun to be magnetized, we must calculate first the number of frictions to which this force corresponds, in order to be able to assign the rank of the subsequent frictions, and the magnitude of the corresponding magnetical forces.

8. When the rubbing bars are greater than the bar to be magnetized, from the first complete friction the force of magnetism is very nearly one-half of the force which the magnetized bar will finally possess.

After the twelfth complete friction, the magnetic force differs little from that which the rubbing bars can communicate.

We owe also to M. Quetelet two interesting memoirs on the magnetic intensity of different places in Switzerland, Italy, Germany, and the Low Countries.

Magnetic influence of the aurora borealis.

Dr Robison.

The influence of the aurora borealis on the magnetic needle, which was observed by Hiorter at Upsal, in 1741, and by Wargentin in 1750, had long induced philosophers to regard it as a magnetic phenomenon; and this was greatly confirmed by the fact that the S. end of the dipping needle points to that part of the heavens to which the rays of the aurora appears to converge. "The aurora borealis," says Dr Robison, "is observed in Europe to disturb the needle exceedingly, sometimes drawing it several degrees from its position. It is always observed to increase its deviation from the meridian; that is, an aurora borealis makes the needle point more westerly. This disturbance sometimes amounts to six or seven degrees, and is generally observed to be greatest when the aurora borealis is most remarkable.

"This is a very curious phenomenon, and we have not been able to find any connection between this meteor and the position of the magnetic needle. It is to be observed, that a needle of copper or wood, or any substance besides iron, is not affected. We long thought it an electric phenomenon, and that the needle was affected as any other body balanced in the same manner would be; but a copper needle would then be affected. Indeed, it may still be doubted whether the aurora borealis be an electric phenomenon. They are very frequent and remarkable in Sweden, and yet Bergman says that he never observed any electric symptoms about them, though in the meantime the magnetic needle was greatly affected.

Van Swinden.

"We see the needle frequently disturbed, both from its general annual position, and from the change made on it by the diurnal variations. This is probably the effect of auroræ boreales which are invisible, either on account of thick weather or daylight. Van Swinden says, he seldom or never failed to observe auroræ boreales immediately after any anomalous motion of the needle; and concluded that there had been one at the time, though he could not see it. Since no needle but a magnetic one is affected by the aurora borealis, we may conclude that there is some natural connection between this meteor and magnetism. This should farther incite us to observe the circumstance formerly mentioned, viz., that the S. end of the dipping needle points to that part of the heavens where the rays of the aurora appear to converge. We wish that this were diligently observed in places which have very different variations and dips of the mariner's needle."

Dr Dalton.

A valuable series of observations on the influence of the aurora borealis on the magnetic needle was made by Dr Dalton, at Kendal and Keswick, during seven years from May 1786 to May 1793, and has been published in his

Magnetic influence of the aurora.

Meteorological Observations and *Essays*, which appeared in 1793. During these observations he noticed the effect which they produced on the magnetic needle, and he was thus led to study the phenomena of the aurora, and to establish beyond a doubt the relation of all its phenomena to the magnetic poles and equator. His views and speculations on this subject we shall detail at some length in a future part of this article; but we shall at present give our readers a specimen of the observations which he made on the magnetic needle during the changes of an aurora.

The aurora appeared at Kendal Feb. 12, 1793, after 6^h P.M., flaming over two-thirds of the hemisphere. The beams converged to a point in the magnetic meridian about 15° or 20° to the S. of the zenith. The following were the changes which he observed in the needle and in the aurora:—

Time.	Variation.	Observations.
5^h 0^m P.M.	25° 5′ W.	
6 35 ...	24 49 ...	altitude of the clear space S. 35°.
6 42 ...	24 55 ...	altitude of ditto 20°, streamers bright, E.
6 50 ...	25 0 ...	streamers bright and active all over the illuminated part.
7 2 ...	25 28 ...	
7 5 ...	25 12 ...	
7 10 ...	24 40 ...	disappeared in the W., active E.
7 20 ...	24 35 ...	active about the zenith, light faint.
7 35 ...	24 45 ...	light faint.
8 0 ...	24 45 ...	strong light northward.
8 10 ...	24 45 ...	a large uniform still light covering half the hemisphere, with flashes now and then.
8 35 ...	24 47 ...	
9 15 ...	24 43 ...	streamers N.W., bright E.; clouds.
9 20 ...	24 43 ...	the *aurora* bursting out openly.
9 30 ...	24 50 ...	as fine and large a display of streamers as has appeared this evening.
10 0 ...	24 55 ...	
10 15 ...	24 57 ...	the light growing fainter and fainter.
10 35 ...	24 40 ...	

In these observations, the deviation produced by the aurora was 53′. In some cases, during the prevalence of auroræ, Dr Dalton did not observe any perceptible disturbance of the needle.

Professor Hansteen.

Professor Hansteen observes, that large extraordinary movements of the needle, in which it traverses frequently with a shivering motion an arc of several degrees on both sides of its usual position, are seldom, perhaps never, exhibited, unless when the aurora borealis is visible; and that this disturbance of the needle seems to operate at the same time in places the most widely separate. "The extent of such extraordinary movements," he adds, "may, in less than twenty-four hours, amount to 5° or 5½°. In most cases, the disturbance is also communicated to the dipping needle; and so soon as the crown of the aurora quits the usual place (the points where the dipping needle produced would meet the sky), the instrument moves several degrees forward, and seems to follow it. After such disorders, the mean variation of the needle is wont to change, and not to recover its previous magnitude till after a new and similar disturbance."

M. Arago.

Magnetic influence of the aurora.

Captain Foster.

Captain Home.

From an extensive series of accurate observations made by M. Arago at Paris since 1818, the needle was almost invariably found to be affected by auroræ that were seen in Scotland; and so striking was the connection between the two classes of facts, that the existence of the aurora could be inferred from the derangements of the needle. M. Arago has likewise discovered, that, early in the morning, often ten or twelve hours before the aurora is developed in a very different place, its appearance is announced by a particular form of the curve which exhibits the diurnal variation of the needle, that is, by the value of the morning and evening maxima of elongation. From a number of corresponding observations on the hourly declination made by M. Arago and M. Kupffer, who established at Kasan, near the eastern limit of Europe, one of Gambey's compasses, similar to that used at Paris, these philosophers were convinced that, notwithstanding a difference of longitude of above 47°, the disturbances produced upon the needle by the aurora took place at the same instant. It is a curious fact, however, and one yet unexplained, that during the frequent occurrence of the aurora at Port Bowen, Captain Foster did not observe any peculiar changes in the direction of the needle, although, from his great proximity to the magnetic pole, the diurnal change sometimes amounted to 4° or 5°; and, under such circumstances, the influence of the aurora ought to have been particularly conspicuous. Mr Christie is of opinion that the direction of the needle may be influenced by the electrical state of the clouds; and he found it to be so in a very distinct experiment which he made for the purpose. Captain Sir Everard Home had observed the same effect produced during thunder-storms; and, in two instances, he found that a needle came sooner to rest during a thunder-storm than it had done either previous or subsequent to it, the number of oscillations having been reduced in one case from 100 to 40, and in another from 200 to 120.

Sir George Back.

During the journey of Captain Sir George Back to the polar regions in 1833, 1834, and 1835, he found that the needle was generally affected by the aurora; and on one occasion the deviation which it produced was 8°. "For nearly a month, however" (previous to the 7th January 1834), he remarks, "the needle had not been perceived to be affected by the aurora, which, it may be proper to observe, was always very faint, apparently high, and generally confined to one point of the heavens."[1] Sir George Back repeatedly observed, that when the aurora was concentrated in individual beams, the needle was powerfully affected; but that it generally returned to its mean position when the aurora became generally diffused. On several occasions the needle was restless, and exhibited the vibrating action produced by the aurora when this motion was not visible; and Sir George Back states that he could not account for this, except by supposing the invisible presence of the aurora in full day.

Mr David Lyon.

The only metals which were formerly supposed to have a distinct and decided power, and were therefore called magnetic metals, are iron, nickel, and cobalt. Mr David Lyon[2] has endeavoured to show that these metals resemble one another, not only in their principal qualities, but in the numerical values of their qualities; and he adds, that whilst these three magnetic substances have the values above referred to nearly equal, there are no other substances in which the same values come very near or fall within those of the three magnetic substances. The values to which Mr Lyon alludes are the following:[3]—

	Specific Gravity.	Atomic Weight.	Atoms contained in a given space.
Nickel	8·27	739·51	1118
Iron	7·21	678·43	1062
Cobalt	7·8	738	1057

The preceding speculation, though ingenious, and deserving of attention, has, however, been overturned by some more recent observations of Dr Faraday. "*Cobalt* and *chromium*," says he, "are said to be both magnetic metals. I cannot find that either of them is so, in its pure state, at any temperature. When the property was present in specimens supposed to be pure, I have traced it to iron or nickel."[1]

---

[1] Appendix to Sir George Back's *Narrative of the Arctic Land Expedition*, &c., p. 601.

[2] *London and Edinburgh Phil. Mag.*, December 1834, p. 415.

[3] M. Pouillet, in his *Elémens de Physique*, tom. iii., p. 89, refers to some remarkable analogies which he has observed between the distance of the atoms of bodies and their magnetic properties.

Dr Faraday.

Dr Faraday published in March 1836 some interesting observations[2] *On the General Magnetic Relations and Characters of the Metals.* He was of opinion that all the metals are magnetic, in the same manner as iron, though not at common temperatures, or under ordinary circumstances. He does not allude to a feeble magnetism, uncertain in its existence and source, but to a distinct and decided power, such as that possessed by iron and nickel; and his impression is, that there is a certain temperature for each metal (well known in the case of iron, beneath which it is magnetic, but above which it loses all power), and that there is some relation between this *point* of temperature and the *intensity* of magnetic force, which the body, when reduced beneath it, can acquire. Iron and nickel would then be no more exceptions from the metals in regard to magnetism, than mercury is in regard to liquefaction.

In order to investigate this point, Dr Faraday subjected various metals in their pure state to a temperature from 60° to 70° below the zero of Fahrenheit, but he could not detect in them the least indication of magnetism. The metals tried were the following:—

Arsenic.
Antimony.
Bismuth.
Cadmium.
Cobalt.
Chromium.
Copper.
Gold.
Lead.
Mercury.
Palladium.
Platinum.
Silver.
Tin.
Zinc.
Plumbago.

Dr Faraday next proceeded to compare iron and nickel with respect to the points of temperature at which they ceased to be magnetic. Iron loses all magnetic properties at an orange heat, and is then to a magnet the same as a piece of copper. Dr Faraday found that the point at which nickel lost its magnetic relations was very much lower than with iron, but equally defined and distinct. If heated and then cooled, it remained unmagnetic long after it had fallen below a heat visible in the dark; and almond oil can bear and give that heat which makes nickel indifferent to a magnet, its demagnetizing temperature being about 630° or 640° Fahr. In order to determine what relation the temperature which took from a magnet its power over soft iron had to that which would take from soft iron or steel its power relative to a magnet, Dr Faraday gradually raised the temperature of a magnet, and found that it lost its polarity rather suddenly when scarcely at the boiling point of almond oil, and then acted with a magnet as cold soft iron. It required to be raised to a full orange heat before it lost its power as soft iron. "Hence," he concludes, "the force of the steel to *retain* that condition of its particles which renders it a permanent magnet, gives way to heat at a far lower temperature than that which is necessary to prevent its particles assuming the *same state* by the inductive action of a neighbouring magnet. Hence, at one temperature, its particles can of themselves retain a permanent state; whilst, at a higher temperature, that state, though it can be induced from without, will continue only as long as the inductive action lasts, and at a still higher temperature all capability of assuming this condition is lost. The temperature at which polarity was destroyed appeared to vary with the hardness and condition of the steel. Fragments of loadstone of very high power were then experimented with. These preserved their polarity at higher temperatures than the steel magnet; the heat of boiling oil was not sufficient to injure it. Just below visible ignition in the dark they lost their polarity, but from that to a temperature a little higher, being very dull ignition, they acted as soft iron would do, and then suddenly lost that power also. Thus the loadstone retained its polarity longer than the steel magnet, but lost its capability of becoming a magnet by induction much sooner. When magnetic polarity was given to it with a magnet, it retained this power up to the same degree of temperature as that at which it held its first and natural magnetism."

M. Pouillet.

Some of the results observed by M. Pouillet[3] stand in opposition to some of the preceding statements. M. Pouillet considers it as certain that there are *five* simple magnetic bodies, viz.:—

Iron,
Manganese,
Nickel,
Chrome, and
Cobalt;

and in consequence of having observed some remarkable analogies between the distance of the atoms of bodies and their magnetic properties, he was led to suppose that the magnetic limit of different bodies ought to be found at very different temperatures. "I have, indeed," says he, "demonstrated by experiment,—1. That cobalt never ceases to be magnetic, or rather that its magnetic limit is at a temperature higher than the brightest white heat; 2. That chrome has its magnetic limit a little below the temperature of dark blood-red heat; 3. That nickel has its magnetic limit about 350° centigrade, nearly at the melting point of zinc; and, 4. That manganese has its magnetic limit *at the temperature of from 20° to 25° below zero.*[4] Experiments," continues he, "on these five magnetic bodies seem to prove, 1*st*, That heat acts upon magnetism only in consequence of the greater or less distance which it occasions between the atoms of bodies; and, 2*d*, That all bodies would become magnetic if we could by any action whatever make their atoms approach within a suitable distance."

Faraday. Para-magnetism and dia-magnetism.

The theory of universal magnetism, as deduced experimentally by Coulomb, has received great modifications from the discoveries of Dr Faraday. In consequence of using magnets of small power, Coulomb found that every body freely suspended between the poles of a magnet took what is called an axial position in a line joining the poles. Dr Faraday, however, has discovered that a large number of bodies place themselves in a position at right angles to the line joining the poles. To the substances possessing this property he has given the name of *diamagnetic;* and that of *diamagnetism* to the peculiar action exerted upon the molecules of bodies by the magnetic forces. Retaining the old name of *magnetism* for the general phenomena of the science, he adopts the following nomenclature:—

Magnetic	Paramagnetic	*Axial* direction, or *attractive.*
	Diamagnetic	*Equatorial* direction, or *repulsive.*

The nature of these forces may be more readily apprehended by supposing a fluid sphere to be placed between the magnetic poles: it would, if *paramagnetic*, be drawn out *axially* into a *prolate* spheroid; and if *diamagnetic*, it would be drawn out equatorially, and form an *oblate* spheroid. Dr Faraday found iron, nickel, cobalt, &c., to be paramagnetic; and bismuth, antimony, zinc, copper, silver, and gold, &c., to be diamagnetic. Hence it is obvious that the universal magnetism of Coulomb is incompatible with the discoveries of Dr Faraday. Among the most interesting results obtained by our distinguished countryman, is his discovery of the magnetic condition of gaseous bodies. Oxygen gas inclosed in a thin envelope was found to be paramagnetic, and drawn like iron into the axial line; while olefiant gas was diamagnetic, and repelled, like bismuth, equatorially. Guided by these results, Dr Faraday has been led to consider all space, whether devoid of matter or occupied by it, as traversed by lines of force operating through it; paramagnetic bodies concentrating parallel lines of magnetic force upon themselves, refracting them, as it were, like rays of light; and diamagnetic bodies expanding the same lines. In the one case the parallel lines are made to approach, and in the other to recede from one another.

[4] M. Pouillet remarks elsewhere, that manganese does not become magnetic till it is cooled down to 15° or 20° below zero. (*El. Phys.* iii., p. 18.)

Professor Gauss. A.D. 1833.

Researches on the intensity of magnetism were made by Professor Gauss of Göttingen, who has given an account of them in a treatise entitled *Intensitas vis Magneticæ Terrestris ad absolutam mensuram revocatis*, published at Göttingen in 1833. His object is to impart to magnetical observations the accuracy of astronomical ones. By observing the oscillations of a magnetized bar, he finds the product of the horizontal intensity of the earth's magnetism, and the static momentum of the free magnetism of the bar; and by eliminating the latter from the two equations, he obtains an absolute measure of the former, independent of the magnetism of the bar. The horizontal intensity thus found is then to be multiplied by the secant of the dip of the needle, in order to give the absolute intensity. In this inquiry Professor Gauss found it necessary to deduce from observation the true law of magnetic action, which, from a number of consistent and carefully made experiments, he found to be in the inverse ratio of the square of the distance. From a series of accurate experiments, Professor Gauss found the horizontal intensity at Göttingen, on the 18th September 1832, to be 1·7821; and taking the exponent of gravity in moving bodies at the place of observation as the unit of force, and using the Paris line and the Berlin pound, he found the absolute horizontal intensity to be 0·0039131; and as he found the dip at Göttingen on the 23d June 1832 to be 68° 22′ 52″, the absolute intensity of terrestrial magnetism will be

$$\text{Sec. } 68^\circ\ 22'\ 52'' + 0{\cdot}0039131.$$

Professor Gauss has proposed and put in practice a very accurate method of observing the daily variation of the needle, and of determining the time of vibration of a needle or magnetized bar. He fixes a plane mirror on the end of the bar, and perpendicularly to its axis, and by observing the reflected image of the divisions of a scale, by the aid of a theodolite placed at a distance, he is able to observe and to measure the minutest changes.

The magnetized bar employed by Gauss is of much larger dimensions than the bar of Prony's magnetic telescope; the small ones, which he uses as magnetometers, being four pounds weight, and the large ones twenty-five pounds; two of which, when fastened together, form the *apparatus or multiplier* of induction for rendering sensible and measuring the oscillatory movements predicted by a theory founded on Dr Faraday's great discovery. By this valuable invention of Professor Gauss, the observer is not under the necessity of approaching the magnetized bar, so that no disturbance is occasioned by the currents of air produced by the proximity of the observer's body, and the observations may be made in the smallest intervals of time.

With apparatus similar to that of Professor Gauss simultaneous observations were made in 1834 and 1836, at intervals of five or ten minutes, at Göttingen, Copenhagen, Altona, Brunswick, Leipzig, Berlin, Milan, and Rome. It appears from the graphic representation of the results, that the smallest inflexions of the horary curves are parallel, and consequently the disturbing causes which produce them simultaneous at Milan and Copenhagen, two of the places of observation, which have a difference of latitude of 10° 13′.

In giving an account of Professor Hansteen's labours, we have briefly noticed his journey to Siberia, and the erection of magnetic observatories by the Emperor of Russia, on the recommendation of Baron Humboldt; and we have also referred to the early researches of this distinguished philosopher. When travelling in the equinoctial regions of America during the years 1799–1804, Baron Humboldt had devoted much attention to the determination of the intensity of the magnetic forces, and of the dip and variation of the needle. Upon his arrival in Europe, he conceived the design of examining the progress of the horary changes of the variation, and the perturbations to which it is subject, by employing a method which had never been adopted on an extended scale. In a large garden at Berlin, he measured, particularly at the period of the equinoxes in 1806 and 1807, the angular alterations of the magnetic meridian, at intervals of an hour, often of half an hour, without interruption, during four, five, or six days, and as many nights. The instrument employed was Prony's magnetic telescope, suspended according to the method of Coulomb, and capable of being reversed upon its axis. It was placed in a glass frame, and directed towards a very distant meridian mark, the illuminated divisions of which indicated six or seven seconds of hourly variation. In these researches Baron Humboldt was struck with the frequency of oscillations whose amplitude extended beyond all the divisions of the scale, and which repeatedly took place at the same hours before sunrise. "These vagaries of the needle," says the baron, "the almost periodical return of which has recently been confirmed by M. Kupffer, in the account of his travels in the Caucasus, appeared to me the effect of a reaction of the interior of the earth towards the surface; I should venture to say, of *magnetic storms*, which indicate a rapid change of tension." With the view of investigating the causes of these disturbances, Baron Humboldt proposed to erect similar apparatus on both sides of the meridian of Berlin; but the political tempest in Germany, and his mission to France by the government, delayed the execution of his plan. M. Arago, however, as we have already seen, began and prosecuted the inquiry with singular success.

Baron Humboldt.

When Baron Humboldt again fixed his residence in Germany in 1827, he erected one of Gambey's compasses in a magnetic pavilion, without any iron, in the middle of a garden, and began a series of regular observations in the autumn of 1828. At his request, the Imperial Academy and the curator of the University of Kasan erected magnetic observatories at St Petersburg and Kasan; and the imperial department for mines established similar stations at Moscow, Burnaoul, and Nertschinsk. The academy, too, sent Mr George Fuss to Pekin, where he procured the erection of a magnetic pavilion in the convent garden of the monks of the Greek church. After Mr Fuss's return, M. Kowanko, a young officer of mines, continued the horary observations corresponding to those made in Germany and Russia. Admiral Greig established one of Gambey's compasses at Nicolaeff, near the Euxine. Baron Humboldt procured the establishment of a magnetic apparatus at the depth of thirty-five fathoms, in an adit in the mines of Freiberg in Saxony. Baron Von Wrangel was also provided with one of Gambey's compasses at Sitka, in one of the Russian settlements. M. Arago caused to be erected, at his own expense, one of Gambey's compasses in the interior of Mexico, where the soil is 6000 feet above the sea. The French minister of marine established a magnetic station in Iceland, and the necessary instruments were sent in the summer of 1836 to Reikiavig; and Baron Humboldt, at the desire of Admiral de Laborde, sent instruments to the Havannah in Cuba, to furnish a magnetic observatory under the tropic of Cancer.

Notwithstanding these insulated attempts to promote the study of terrestrial magnetism, so creditable to the individuals who made them, some more general and systematic organization of a national or European character was required. On the accession of Lord Grey's government to power in 1830, the writer of this article was requested by a distinguished member of it to suggest any measures which would be useful to science and improve the position of its cultivators. Among these, some of which were carried into effect, was the establishment of physical observatories in different parts of the British empire. The scheme was also brought before the British Association, but no decided step was taken till the year 1836, when Humboldt, in a letter to the Duke of Sussex, urged the erection of physical observatories in the British dependencies. The British Association and the Royal Society united their influence in the same cause; and the government, with an unexampled liberality, organized, as M. Kupffer expresses it, "the most gigantic scientific enterprise that had ever been conceived." The expedition to the South Pole, under Captain Sir James Ross, which sailed in September 1839, was agreed to; and arrangements were made for the establishment of magnetical observatories at Kew, Greenwich, Dublin, Toronto, St Helena, the Cape of Good Hope, and Hobart Town in Van Diemen's Land; and the court of directors of the East India Company authorised the erection of similar establishments at Simla, Singapore, Madras, and Bombay.

Magnetic Conference at Göttingen, A.D. 1839.

In order to organize this important enterprise, General Sabine and Dr Lloyd were deputed to repair to Berlin and Göttingen, to confer with Humboldt and Gauss; and also to St Petersburg, to put themselves in communication with the Russian government. This last journey, however, was rendered unnecessary. M. Kupffer was sent to Göttingen, by order of the emperor, to attend the conference, and to offer to the English philosophers the co-operation of the Russian observatories. The conferences of the magnetic congress began on the 15th October 1839, and the observations to be made at the different observatories were then finally arranged.

Appreciating the liberality of England, and stimulated by its example, the Russian government proceeded, under the direction of M. Kupffer, to erect observatories at different stations which had been fixed upon, and they were in due time completed at St Petersburg, Catherinebourg, Burnaoul, Nertschinsk, Tiflis, Sitka (on the N.W. coast of America), Helsingfors, and at the Russian mission-house in Pekin, in China. The English government furnished instruments for the observatories at Breslau, Hammerfest, Cairo, and Algiers; and magnetic observatories have been established at Berlin, Breda, Brussels, Copenhagen, Göttingen, Gotha, Hanover, Heidelberg, Leipzig, Marbourg, Milan, Munich, Philadelphia, Prague, and Upsal. The Austrian government has erected similar observatories under the superintendence of Dr Kreil; and Prussia has done the same at various stations from Memel to the Rhine.[1]

Although France, from reasons which it is not easy to understand, took no part in this great scientific movement, yet individual members of the Institute took an active part in establishing magnetical observatories on a limited scale. So early as 1823 M. Arago erected, in the garden of his observatory, a small building for magnetical observations; and at his request M. Kupffer made corresponding observations at Kazan in 1825 and 1826, thus anticipating the great movement afterwards made in England; but as no previous consent had been made respecting the days and hours of observation at these two stations, "it was only," as M. Kupffer observes, "by accident that the irregular motions of the two needles were shown to be simultaneous." Magnetical observations were carried on for some time at Montrouge, St Denis, Vincennes, and St Cloud, but they have not led to any important results.

The attention of the French government having been recently directed by M. Count de Vaillart, the distinguished minister-at-war, to the importance of meteorological observations in reference to the culture of cottons and other purposes in Algiers, the subject was brought before the Academy of Sciences in 1853, and more recently in 1855; when, after a violent opposition on the part of M. Biot[2] to the establishment of meteorological observatories, it was resolved to adopt the project of the government; and arrangements are now making for a complete system of magnetical observations at Paris and other places, and for making Algiers the centre of a similar system in the N. of Africa.

Researches of General Sabine.

Notwithstanding the rash and incorrect statement of M. Biot, that no real fruit had been obtained from the magnetic observations, most valuable results had been obtained several years before, with which he must have been acquainted. In the able hands of General Sabine, the Toronto and Hobart Town observations had led so early as 1851 to the discovery of important laws. In three interesting papers "On the Periodical Laws discoverable in the mean effects of the larger Magnetic Disturbance," he has shown that this disturbance, which is of large amount, and apparently of irregular occurrence, and to which the name of *magnetic storms* has been given, is, when studied in its mean effect, governed by periodic laws of systematic order and regularity, and exhibits periods whose duration is respectively,—1st, a solar day of 24 hours; 2d, a solar year of 365 days; and, 3d, *a period of about* TEN *of our solar years, corresponding both in duration, and in the epochs both of* maximum *and* minimum *variation, to the approximately* decennial *period discovered by Schwabe in the phenomena of the solar spots.*[3] Hence we may conclude that the sun is a great magnet, communicating to the earth its magnetic properties as well as its temperature, and having a force varying with the solar spots as indicating disturbances in its own atmosphere. Sir William Herschel endeavoured to show that the heat of the sun, as indicated by a good harvest or the low price of wheat,[4] varies with the solar spots; and it is a new argument in favour of the connection between the magnetic poles and those of maximum cold, that the magnetism of the earth, as well as its heat, varies with the number of spots or openings on the sun's atmosphere.

---

[1] The Russian government has already (1856) published 14 quarto volumes, containing the magnetical and meteorological observations made at their observatories since 1840; and the British government has also published several volumes, containing the observations made at Toronto, St Helena, the Cape, and Hobart Town. These valuable works, many of them illustrated with numerous plates containing drawings of the instruments employed, and diagrams exhibiting to the eye the various results of observations, have been liberally presented to the principal scientific institutions in the Old and New World.

[2] M. Biot characterized the gigantic works published in Russia and England as "*large and expensive volumes filled with cyphers;*" and he had the hardihood to say "*that neither in Russia nor anywhere else has any* REAL *fruit been obtained from these costly publications,*" and that "*they can produce nothing but masses of disjointed facts, materially accumulated, and without any useful purpose in view, either for theory or its applications.*" (See *Comptes Rendus*, vol. xli., p. 1180. Dec. 31, 1855.)

[3] *Phil. Trans.* 1851, art. v.; 1852, art. viii. In these papers the periodical laws were deduced from the disturbances in the magnetic declination; but in a more recent memoir, read on the 14th February 1856, General Sabine has shown that the same laws regulate the disturbances of the magnetic inclination and the magnetic force.

[4] As the price of wheat depends upon many other causes than the summer heat, it is hardly an approximate measure of the temperature by which grain is ripened. It would therefore be advisable to compare the phenomena of the solar spots with the actual temperature of the seasons throughout the globe, in so far as it can be obtained from meteorological registers.

Influence of the moon on the magnetic needle.

Among the other grand results of our magnetic establishments we must rank the discovery of the moon's influence on the magnetic elements of the earth. Dr Kreil[1] seems to have first recognised the moon's influence upon the magnetic needle in the magnetical observations made at Prague in 1839 and 1840. Mr Broun obtained a similar result from the observations made at Makerstoun, in Scotland, and traced periodical laws, dependent not only upon the moon's hour angle, but upon her declination and distance from the earth. Believing that the sun influenced the earth's magnetism mainly, if not entirely, by its thermal influence, Dr Lloyd could hardly believe that the moon, whose heat was insensible, could exert any magnetic influence. Upon discussing the Dublin observations, however, he obtained results in accordance with those of Kreill and Broun in so far as the magnetic declination was concerned.[2] In a subsequent paper Dr Lloyd determined the law of the moon's action, the north pole of the needle deviating twice to the E. and twice to the W. in the course of the lunar day, and the maxima occurring one or two days after the syzigies, and the minima one or two days after the quadratures.[3] In a third paper he has shown that the moon exercises an influence upon the horizontal component of the magnetic intensity.[4] Dr Lloyd found that the effect of the moon upon the declination was to that of the sun as 1 to 13; and that the extreme variation of the morning range is 1′·85, and that of the evening one 1′·60; their mean variations being 1′·60 and 1′·20 respectively.

The discussion of the observations at Toronto by General Sabine has enabled him to determine with greater accuracy the influence of the moon on the earth's magnetism. From five years' observations made hourly, General Sabine has drawn the following conclusions:—"1. The three magnetic elements concur in showing that the moon exercises a sensible magnetic influence at the surface of the earth, producing in every lunar day a variation which is distinctly appreciable in each of the three elements by the instruments employed. 2. That the lunar diurnal variations in each of the three elements constitutes a double progression in each lunar day, the declination having two easterly and two westerly *maxima*, and the inclination and total force each two maxima and two minima between two successive passages of the moon over the astronomical meridian; the variation passing in every four times through *zero* in the lunar day. The approximate range of the lunar diurnal variation at Toronto is 38″·33 in the declination, 4″·4 in the inclination, and ·000012 parts of the total force. 3. That the lunar diurnal variation thus obtained, appears to be consistent with the hypothesis that the moon's magnetism is, in great part at least, if not wholly, derived by induction from the magnetism of the earth. 4. That there is no appearance in the lunar diurnal variation of the *decimal* period which constitutes so marked a feature in the solar diurnal variations."[5] These important results have been deduced from 106,619 observations, namely, 40,503 of the declination, 34,303 of the horizontal force, and 31,773 of the vertical force.

CHAP. II.—ON THE GENERAL PHENOMENA AND PROPERTIES OF MAGNETIC BODIES.

General properties of magnetic bodies.

A body is said to be magnetic when it has the power of attracting soft iron, either in the subdivided state of iron filings, or in large portions; or of attracting and repelling other magnetic bodies like itself: of taking a particular position when freely suspended, or moving on a pivot: and of communicating magnetism either temporarily to soft or permanently to hard iron in the form of steel. Hence we may arrange the general properties of magnetic bodies under the following heads:—

1. On the attractive power of magnetic bodies upon soft iron.
2. On the attractive and repulsive power of magnets over each other, or over iron either temporarily or permanently magnetized.
3. On the effect of masses of iron on the attractive force of a magnet.
4. On the polarity of magnetic bodies.
5. On the power of magnets to communicate magnetism to other bodies.
6. On the distribution of magnetism in artificial magnets.
7. On the effect of division and fracture on the distribution of magnetism.
8. On the magnetic charge.
9. On magnetic figures.

SECT. I.—*On the Attractive Power of Magnetic Bodies upon Soft Iron.*

Attraction of magnets over iron.

The natural magnet or loadstone was for a long time the only body considered as possessing magnetic properties. It is an ore of iron, of a grey colour, and a dark metallic lustre. Its specific gravity is about four and a half times that of water. It crystallizes in the form of the regular octahedron, and it consists of from 85 to 75 parts of iron, and from 15 to 25 parts of oxygen. It is found in almost every part of the world,[6] and often forms rocks of considerable magnitude; but different specimens of it possess very different powers of attraction.

Loadstone.

The smallest loadstones generally have a greater attractive power in proportion to their size than larger ones. They have been found of such strength, that though weighing only about 25 grains, they could lift a piece of iron about forty times heavier than themselves. A small magnet set in a ring, and worn by Sir Isaac Newton, is said, but we know not on what authority, to have been capable of lifting 746 grains, or 250 times its own weight; and it is stated by Cavallo, that he has seen a loadstone which weighed only about 6½ grains, which lifted a weight of 300 grains. A magnet weighing 38 lb., and which was found in 1781 to sustain above 200 lb., was presented to John V. of Portugal by the Emperor of China.

Natural loadstones often possess unequal powers of attraction in different parts of their mass, in consequence of want of homogeneity of structure and composition; and hence a portion has often been cut from a large loadstone which could lift a greater weight of iron than the large one itself, the portion detached having possessed the most suitable structure, and the other part having weakened the action of the powerful part by keeping the body to be lifted at a greater distance from those points where the magnetism was strongest. It is, no doubt, from a similar cause that small magnets have a greater proportional power than large ones, or that those of 2 lb. weight have seldom been found capable of lifting more then *ten* times their own weight of iron.

If we now take a natural loadstone L, however shapeless,

[6] According to Norman, the best loadstones were those brought from China and Bengal.

General Properties of Magnetic Bodies.

and after rolling it in a quantity of iron filings afterwards withdraw it, we shall find that the filings are accumulated more abundantly in two opposite points A, B, than in any other, as shown in fig. 1. These two points A, B, are called the poles of the magnet, and are the points of greatest attraction. When either of these poles is held at a distance from the iron filings, the filings will be attracted to it, and will adhere with such force that it is difficult to brush them off.

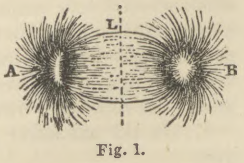

Fig. 1.

If we suspend a small needle of iron or steel by a fine linen or silken fibre, or balance it on a pivot, and bring the poles of the loadstone L near it, it will be attracted to it in the first case, or will oscillate on its pivot in the second case.

If we make the needle float on water in a glass tumbler, and bring any pole of L on the outside of the tumbler, the needle will be attracted towards the pole, notwithstanding the interposition of the glass; and by using the needle upon a pivot, it will be found that the attractive force of the loadstone is in no respect diminished by the interposition of any substance whatever, except iron; conductors and non-conductors of electricity having no effect whatever in stopping or diminishing the action of the loadstone, unless the interposed body be iron, or contains iron in any of its metallic states.

While the loadstone thus attracts iron, and all bodies containing it in a metallic state, these same bodies exercise a reciprocal attraction upon the loadstone, action and reaction being equal and opposite. The truth of this may be exhibited by suspending a magnet, and bringing into the vicinity of its poles a piece of soft iron. The magnet will be gradually attracted by the iron, in the same manner as if the iron had been suspended and a pole of the magnet held near it.

Armature of loadstones.

The power of natural loadstones is greatly increased by what is called an *armature*. After finding the poles of the loadstone, the opposite faces which contain them should be ground off, and the mass wrought into a regular shape, armed, as explained in chap. x., sec. 12.

SECT. II.—*On the Attractive and Repulsive Power of Magnets over each other, or over Iron either temporarily or permanently magnetized.*

Attraction and repulsion of magnets.

If we suspend near each other two loadstones, AB, A′B′ (as represented in fig. 2), by two threads T, T, we shall find by changing the relative position of their poles, AB, A′B′, that there are certain positions in which these poles attract each other, and others in which they are repelled. By marking the poles which attract each other, such as A, B′ and A′, B, we shall find that the poles which repel each other are A, A′ and B, B′, and that this mutual attraction and repulsion takes place under every change of circumstances.

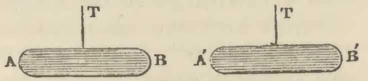

Fig. 2.

If we suspend a piece of soft iron *ab* from a loadstone AB, we shall find that the end *b* of the iron exercises the same attractive and repulsive power upon the poles A′, B′ (fig. 3), of a suspended magnet that B did; and in like manner, if the piece of iron *a′ b′* is suspended from the pole A′, the end *a′* will exercise the same attraction and repulsion upon the poles of a suspended magnet that A′ did.

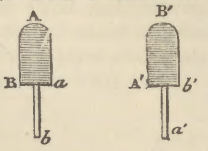

Fig. 3.

SECT. III.—*On the effect of Masses of Iron on the Attractive Force of a Magnet.*

General Properties of Magnetic Bodies.

Effect of masses of iron on the attractive force.

If we suspend a piece of iron C from the arm of a balance, it will be attracted by the pole P of a magnet A, and will descend towards P in virtue of this attraction. If we now place a mass of iron I close to A, the suspended iron C will rise, as if the attractive force of P were diminished. This power of the mass of iron I seems only to extend to a given point within the magnet A, the distance between the magnet and the iron remaining the same; for if the iron C is suspended above a point x at some distance from P, the action of I will not be felt at the point x, except by diminishing the distance between P and C, or by increasing the neutralizing power of the mass I.

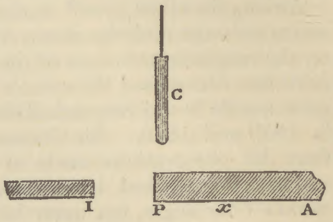

Fig. 4.

Sir William Snow Harris, to whom we owe this experiment, has shown that a similar effect is produced when the iron I is placed between the magnet P A and the suspended iron C, and also when I is placed below P. In the first of these cases I stops the attraction of P upon C, and acts as a screen.

Sir William has observed a very curious result of the action of iron upon a magnet. If we join the poles of a bar-magnet by a piece of soft iron, which is called its *keeper* or *armature*, the power of the magnet is preserved and increased; but if we envelope the bar completely in soft iron, its power is decreased. In a hollow cylinder of soft iron, Sir William placed a cylindrical magnet which fitted it accurately. The force of the inclosed magnet having been previously carefully measured, its power was found greatly diminished when it was withdrawn. Sir William found the decrease so great, that he believes the power of the magnet might be thus entirely annihilated by a careful arrangement of the experiment.

SECT. IV.—*On the Polarity of Magnetic Bodies.*

Polarity of magnets.

If we suspend a loadstone, as in fig. 2, or make it float upon water or mercury, by placing it on a thin plate of cork or wood, it will gradually change its place till it rests in a position where a line joining the poles A, B is nearly north and south. This is, generally speaking, the case in Europe; the end A, which points northward, deviating in some places from the meridian to the west, in some places to the east; while in other parts of the globe it points exactly to the north. The deviation of the loadstone from the meridian is called its *declination*, or *variation*. This property of the magnet is called its *polarity*, or *directive power*; and the pole A, which turns to the north, is called its *north pole;* and the pole B, which turns to the south, its *south pole.* It will now be found that the poles and magnets A, A′, or B, B′, which repel each other, are either both *north* or both *south* poles; and that the north and south poles attract each other. Hence there are in magnetism, as there are in electricity, two opposite powers or principles, namely, the *northern* and the *southern*, or boreal and austral magnetism; and, as in electricity, a *repulsion* takes place between the two powers of the *same* name, and *attraction* between the two powers of an *opposite* name.

The magnetism from which loadstones derive their polarity, or their tendency to direct themselves to particular points of the compass, is obviously derived in some way or other from the earth or its atmosphere; and hence it is called the *Magnetism of the Earth, or Terrestrial Magnetism,* which will be treated more fully in a future part of this article.

SECT. V.—*On the Power of Magnets to communicate Magnetism to other Bodies.*

Communication of magnetism.

We have already seen, that if a piece of soft iron is suspended to a magnet by the attraction of one of its poles, the iron becomes magnetic, but only during the time that it is in contact with the loadstone. But if we use a piece of hardened iron, or steel, *ab*, and suspend it as in fig. 3, it will be found to have acquired a permanent magnetism, the strength of which will depend on the power of the natural magnet AB, and on the time which the steel bar has been suspended. The pole *a* will be a *north* pole similar to A, and the pole *b* a *south* pole similar to B; and the little magnet *ab* will possess all the properties of the natural magnet, such as attraction for soft iron, and polarity; and its action upon another little steel magnet *a'b'*, made in a similar manner, will be the same as the action of two natural magnets upon each other. A steel magnet thus made is called an *artificial magnet;* and we shall in the sequel consider the magnets of which we speak as steel bars rendered permanently magnetic.

A little magnet *ab* has been made by a very simple process, namely, that of contact with the pole of a natural magnet; but there are more complex and efficacious methods, by which a very high degree of permanent magnetism can be communicated to steel, which will be fully explained in the practical part of this treatise.

In order to communicate magnetism from a natural or artificial magnet to unmagnetized iron or steel, it is not necessary that the two bodies be in contact. The communication is effected as perfectly, though more feebly, when the bodies are separated by space.

Magnetic induction.

If the *north* pole N of an artificial steel magnet A is placed near the extremity *s* of a piece of soft iron B, the end *s* will instantly acquire the properties of a *south* pole, and the opposite end *n* those of a *north* pole. The opposite poles would have been produced at *n* and *s* if the south pole S of the magnet A had been placed near the iron B.

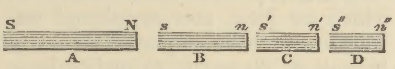

Fig. 5.

In like manner, the iron B, though only temporarily magnetic, will render another piece of iron C, and this again another piece D, temporarily magnetic, north and south poles being produced at n', s', and n'', s''.

The magnetism inherent in B, C, and D, is said to be *induced* by the presence of the real magnet A, and the phenomena are exactly analogous to the communication of electricity to unelectrified bodies by induction, the positive state inducing the negative, and the negative the positive, in the parts of a conductor placed in a state of insulation near an electrified body.

In order to show by simple experiments that soft iron is itself a magnet while placed near a magnet, let A be a magnet, and K a key held near its lower edge; a nail N will remain suspended by virtue of its induced magnetism; but if A is withdrawn, or K removed from A, the nail N will instantly fall, the induced magnetism diminishing with the distance.

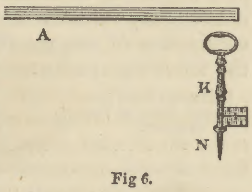

Fig 6.

If we hold the key K above a portion of iron filings, they will not be attracted by it; but if we then bring the magnet A near the ring of the key, as in the figure, the iron filings will instantly start up, and be attracted by the key.

Reaction of iron on magnets.

We have already noticed, in Sect. I., that the iron attracted by a magnet reacts upon the magnet, and attracts it in return. The same is the case with a bar of iron on which magnetism is induced. It reacts on the magnet which induces its magnetism, and increases its magnetic intensity. Hence we derive a distinct explanation of the remarkable facts, that a magnet has its power increased by having a bar of iron placed in contact with one of its poles, and that we can gradually add more weight to that which is carried by a magnet, provided we make the addition slowly and in small quantities; the power of the magnet being increased by the reaction of each separate piece of iron that it is made to carry.

Consecutive poles.

If the bar of iron on which magnetism is induced is long, and the strength of the magnet great, a succession of poles is produced along its length, a north pole always following a south pole, and *vice versa.*

Magnetic attraction and repulsion explained.

These facts enable us to explain the phenomena of magnetic attraction and repulsion, which are necessary consequences of magnetic induction. The magnet attracts a piece of iron by inducing an opposite polarity at the end in contact with it, and the two opposite principles attract each other. In like manner, the north pole of one magnet attracts the south pole of another, and similar poles repel each other, in consequence of the attraction and repulsion of the opposite or similar principles. The attraction of iron filings is explained in the same manner. The particle of iron next the magnet has magnetism induced upon it, and it becomes a minute magnet, like B in fig. 5. This particle again makes the next particle a magnet, like C, and so on; the opposite polarities in each particle of the filings attracting one another, as if they were real magnets.

In comparing the amount of the *attractive* force of two *dissimilar* poles of two magnets with the amount of the *repulsive* force of the two similar poles, it has been found that the former force is considerably greater than the latter. This result is a necessary consequence of the inductive process above described. When the two attracting poles are in contact, each magnet tends to increase the power of the other, by developing the opposite magnetisms in the adjacent halves, and thus increasing their mutual attraction. But when the two repelling poles are brought into contact, the action of each half brought into contact has a tendency to develop in that half a magnetism opposite to that which it really possesses, and thus to diminish the two similar principles, and weaken their repulsive power. This injurious influence of opposite poles upon the repulsive power of the magnets in action is finely exhibited when one of the magnets is very powerful, and the other very weak. When the two similar poles are held at a moderate distance a repulsion is distinctly exhibited; but when they are brought into contact, the stronger *attracts* the weaker magnet, an effect which is produced by its actually destroying the similar weak magnetism in the half next it, and inducing in that half the opposite magnetism, which, of course, occasions attraction.

When the magnet A and the piece of iron B are placed in the same straight line, as in fig. 5, the pole N acts favourably in inducing south polar magnetism at *n*, and north polar at *s;* but it is evident that the remote pole S must tend to weaken the inductive force of N, by inducing, though in a feeble degree, north polar magnetism at *n* and south polar at *s*. If the soft iron B is placed as in fig. 7, the induced magnetism will be nearly as strong as before, the greater proximity of N tending to produce south polar magnetism in *n*, being compensated by the increased proximity of S tending to produce north polar magnetism in *n*. In the inclined position C the induced magnetism is still stronger, as S acts more powerfully upon *n;* and when the two are parallel, as in fig. 8, the two bars or magnets are in the position most favourable for developing and sustaining the magnetism which they receive or possess.

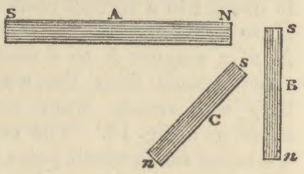

Fig. 7.

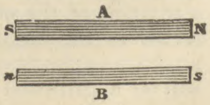

Fig. 8.

General Properties of Magnetic Bodies.

Hitherto we have considered the natural and artificial magnet as producing magnetism in soft or hard iron, distributed in the same manner as in the inducing magnet; but by the action of one or more magnets we can distribute the magnetism in various ways, as follows:—

In the case of bars, we may have a north pole in the middle of it, and a south pole at each extremity. Thus, in fig. 9, if the magnet NS has its north pole N placed opposite the middle of the soft iron bar *nn*, this bar will have a south pole at *s*, and north poles at *n*, *n*. The very same effect will be produced if, as in fig. 10, we place the soft iron bar B between two magnets A, C, whose north poles N, N, tend to produce south poles at *s*, *s*, and consequently northern polarity in the middle at *n*. In the preceding case, a south pole may be produced in the middle, and north poles at the ends of the bar, by placing the south poles of the magnets where the north poles are placed.

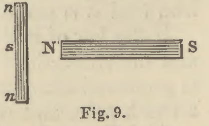

Fig. 9.

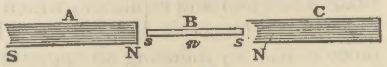

Fig. 10.

In like manner, a piece of soft iron *ss*, *ss*, of the form of a cross, will have south poles at *s*, *s*, *s*, *s*, if the south pole S of a magnet A is placed on or near its centre, as in fig. 11; as it may be conceived to consist of two bars *ss*, *ss*. For the same reason, if a circular plate of soft iron is substituted in place of the cross *ss*, *ss*, and the south pole S of the magnet placed upon or near its centre, that centre will be a north pole, and every point of the circumference of the plate will be a south pole.

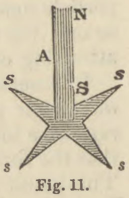

Fig. 11.

A very instructive experiment, founded on magnetic induction, is exhibited in fig. 12, where several soft-iron wires or slender bars *sn*, *sn*, *sn*, are suspended at the north pole N of a magnet N. Each of the ends *s*, *s*, *s*, becomes a south pole by induction from the action of the north, and consequently the lower ends *n*, *n*, *n*, north poles. The south poles *s*, *s*, *s* have a tendency to repel each other, but are prevented from yielding to their repulsive forces in consequence of their strong adhesion to the north pole N. The north poles *n*, *n*, *n*, however, are free from this restraint, and exhibit their mutual repulsion by their diverging as shown in the figure. Hence we see the reason why rows of iron filings adhering to each other, when attracted by a magnet, keep separate from each other by the repulsive forces of the similar poles.

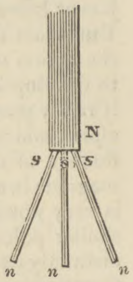

Fig. 12.

In the following form of the experiment given by Cavallo, the repulsion of both poles is well illustrated. If we suspend two short pieces of soft iron wire *ns*, *ns* by threads, they will hang in contact in a vertical position. If we now bring the north pole N of a magnet A to a moderate distance from the wires, they will recede from each other, as in fig. 13. The ends *s*, *s* being made south poles by induction from the north pole N, will repel each other, and so will the north poles *n*, *n*. This separation of the wires will increase as the magnet A approaches nearer them; but there will be a particular distance at which the attractive force of N overcomes the repulsive force of the poles *s*, *s*, and causes the wires to converge, as in fig. 14, the north poles *n*, *n*, still exhibiting their mutual repulsion.

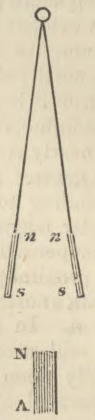

Fig. 13.

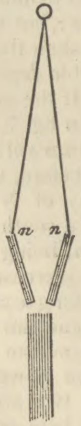

Fig. 14.

General Properties of Magnetic Bodies.

The neutralization or destruction of induced magnetism, by two equal and opposite magnetic actions, is shown in the following experiment, given by Dr Robison. If we take a forked piece of soft iron CDE, and suspend it by the branch D from the north pole of a magnet B, it will be magnetized by induction, and will carry a key at its lower end E, which will be a north pole. If we now apply to the other branch C the south pole S of another and equal magnet A, the key will instantly drop off. This obviously arises from the south pole S inducing a south pole at E, which either destroys or neutralizes the north polar magnetism previously induced by N.

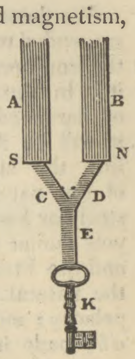

Fig. 15.

Sect. VI.—*On the Distribution of Magnetism in Artificial Magnets.*

Distribution of magnetism.

It is very obvious from the preceding experiments that in regular magnets, with a north pole at one end and south pole at the other, the two kinds of magnetism, north polar and south polar, are equally and regularly distributed, the one occupying one-half of the magnet, and the other the other half. It is obvious, also, that each kind of magnetism has no intensity at the centre of the magnet, or its middle part, and that it increases, according to some regular law, from that point towards the two poles at the extremities of the magnet.

Coulomb's experiments.

The first person who determined the law of distribution which we have now mentioned was M. Coulomb. The magnet which he employed for this purpose was a cylinder 2 lines in diameter, 27 inches long, and its weight 1946 grains; and he ascertained the intensity of magnetism at each point, from its middle to its extremity, by observing the number of oscillations which a small magnetic needle performed in a minute, when it was made to oscillate before different points of the wire. He had previously observed the number of oscillations which the same needle performed out of the sphere of the magnet, and he considered the magnetic intensity as proportional to the difference of the squares of those two numbers of oscillations. The first needle which he employed was 3 lines in diameter and 6 lines long; and it was made of such a size, and of such hardness, that its magnetism should not be perceptibly altered by the action of the wire during the experiments; for if any change did take place, the results obtained at different points of the magnet could not be compared. The great length of 27 inches was given to the magnet, in order that its remoter pole might be so distant from the needle that it would be unnecessary to make any allowance for its action upon the oscillations of the needle. In this way Coulomb obtained the following results:—

Distances from the North Pole of the Magnet.	Observed intensity of the Magnetism at these distances.
0	165
1	90
2	48
3	23
4, 5	9
6	6

The distribution of the magnetism is exhibited in fig. 16, where AN is half of the magnet, and N its north pole; and the ordinates to the curves represent the intensities in the preceding table.

These experiments were repeated by Coulomb, with magnets of the same shape and diameter, but of a less length, all other circumstances being unchanged, and he obtained nearly the same results for the three inches of the magnet

General Properties of Magnetic Bodies.

nearest N; and hence he concluded, that whatever was the length of the magnet, provided it was greater than 6 or 7 inches, the 3 inches at both its north and south poles gave always the same results as the 27-inch magnet. From this point towards the centre, the magnetism became weak and insensible in all of them; and, in very long magnets, he even found that the ordinates sometimes passed from positive to negative.

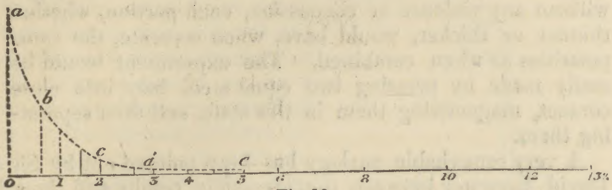

Fig. 16.

M. Biot has remarked that the curve of intensity, as determined by Coulomb, results from the combination of two logarithmic curves ACB′, A′CB, which, setting out from each pole A, B of the magnet AB, would have their ordinates equal and in an opposite direction, as shown in fig. 17. The intensities calculated upon this supposition agree exactly with the observed results.

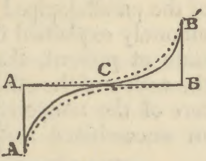

Fig. 17.

Becquerel's experiments.

As Coulomb had examined the distribution of magnetism only in magnets of considerable size, M. Becquerel[1] was desirous of ascertaining if the law was observed in steel wires of a small diameter, such as $\frac{1}{80}$th of a millimetre, or $\frac{1}{2000}$th of an inch. In order to procure such wires, he incased a steel wire, 1 millimetre in diameter, in a cylinder of silver, and having drawn out the whole into a wire, the silver was removed by means of boiling mercury. He employed the method used by Coulomb in determining the law of distribution; but on account of the fineness of the wires, and the weakness of the magnetism which they acquired, he was obliged to make some changes in the method. He obtained, however, the very same results as those given by Coulomb.

Kupffer's experiments.

A number of interesting experiments on the distribution of magnetism were made by M. Kupffer of Kasan,[2] by means of the method of Coulomb. He employed a flat and very narrow needle 12 millimetres long, and he placed it at a horizontal distance of 3 decimetres from a cylindrical bar-magnet of cast steel not tempered, 607 millimetres long, and 12½ millimetres thick. He began his experiments with magnets that possess a weak degree of magnetism. In magnetizing them, he rubbed the steel bar perpendicularly on the north pole of a very strong artificial magnet, and replaced the bar vertically before the needle, the north pole of the bar being uppermost. He found that the south pole was stronger than the north, and that the point of indifference, or the neutral point, was nearer the stronger pole than the other. Upon reversing the magnet, the magnetic intensities of its different points increased, and the neutral point approached the middle of the magnet. These changes were produced successively, and the magnet did not attain its final state till it had remained some time in the same position. Kupffer observed, that whenever the magnetic intensities of the bar increased, the neutral point slowly approached the middle point; that this point was always nearer the stronger pole; that a bar magnetized vertically was always more powerful when its north pole was downwards; and that a bar magnetized by the method mentioned above was always strongest in the pole immediately produced by that of the magnet.

After detailing his observations with a bar magnetized to saturation, he proceeds to determine the influence exercised by the form of the extremities of the bar on the magnetic intensity, and on the position of the neutral point. A cylindrical bar of steel, cast, but not tempered, having been rounded at one of its ends, and magnetized to saturation, was placed 14 centimetres from a magnetic needle, and in the line of its direction. When its north pole was directed to the south, the force of the rounded north pole was 2·0319, and that of the south pole was 2·1558. In the opposite position of the bar, the magnetic force of the north pole was 2·2198, and that of the south pole 2·3006, the neutral point being in the middle.

The rounded end of the bar was now filed to a point, and made sharper and sharper in every successive experiment, after being each time magnetized to saturation. The force of the sharpened pole diminished with its acuteness. The neutral point receded always from this extremity.

This interesting subject has been more recently investigated by Hansteen and Sir W. S. Harris. According to Hansteen, the intensity of any magnetic particle in a bar magnet situated in the axis, is directly as the square of its distance from the middle point of that axis, or the centre of the magnet; while it results from Sir William Harris's experiments "that the magnetism in different points of a regularly tempered and magnetized steel bar is directly as the distance from the magnetic centre; whilst the reciprocal force between any given point and soft iron is as the square of the distance from that centre."[3]

Distribution of magnetism in the interior of magnets. Coulomb's experiments.

In order to ascertain the distribution of magnetism in the interior of magnets, Coulomb formed sixteen rectangular magnets out of the same piece of steel. Each was 6 inches long, 9½ lines wide, and 382 grains in weight. They were annealed at a white heat without being tempered, in order that he might be certain of having them always in the same state. He magnetized them all to saturation, and formed bundles with a certain number of them, similar poles being placed together. The magnets in each bundle were bound tightly together with a strong silk thread. Each bundle was then placed in a torsion balance, and placed 30° out of the magnetic meridian. The force of torsion necessary to retain it in this position was a measure of its magnetic intensity. The following were the forces or degrees of torsion necessary to keep the different bundles at rest:—

	Degrees of Torsion.
1 magnet	82°
2 magnets united	125
4 magnets „	150
6 magnets „	172
8 magnets „	182
12 magnets „	205
16 magnets „	229

Hence it follows that the magnetic force of each bundle increases in a ratio much less than that of the number of plates.

Coulomb next determined the magnetic state of each of the magnets composing the bundles of eight and sixteen magnets; and he found that the two outermost magnets, those which formed the surface of the bundles, had a much greater force than the rest.

The first had a force which measured	46
The second	48
And the mean force of all the rest was	30

A single magnet had its directing force 82°, while for sixteen of them united the mean directing force of each was only 14°·3, that is, about the sixth part of the other.

In examining the bundle of eight magnets by the method of oscillation, he found that the two outermost performed twenty oscillations in 90½ minutes, while all the rest performed the same number in from 211 to 278 nearly, showing the weakness of their magnetism. It is curious that the outermost but one had its poles reversed.

Coulomb also found that a bundle of magnets will take nearly the same degree of magnetism as a single magnet of the same shape and weight; which leads us to believe that, in magnets of one piece, the magnetism diminishes from the surface to the centre, as in the preceding bundles of magnets.

SECT. VII.—*On the Effect of Division and Fracture in the Distribution of Magnetism.*

Effects produced by breaking magnets.

As no natural or artificial magnet has ever been seen with only one pole, or one kind of magnetism, it became interesting to determine experimentally the distribution of magnetism in a part of a magnet cut from its north or south extremity. This experiment has been often made, both by cutting it through at the middle or neutral point, or by cutting or breaking off a portion from the end of it. If NS, for example, is a magnet, N its north and S its south pole, and ACB the curve representing the intensity of its magnetism; then, if we cut it through the middle, C, each half *ns*, *n′s′* will be a complete magnet, with a north pole at *n*, and a south one at *s*, and their neutral points at *c*, *c′*; the curves at *acb*, *a′c′b′*, representing the distribution of their north and south polar magnetism, being similar to the curve ACB of the large magnet of which they are the halves.

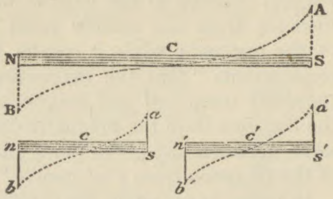

Fig. 18.

When Æpinus made this curious experiment, he did not divide the magnet in two, but he set two steel bars end to end, and magnetized them as one magnet; so that this compound magnet had its magnetism distributed as in a single bar, like NS, fig. 18. He then separated them, and found that each bar was a perfect magnet, with two poles. Dr Robison repeated this experiment successfully on some occasions; but he sometimes found indications of the compound magnet acting as two magnets. We are persuaded that this arose from an imperfect union of the two bars, and not from any defect in Æpinus's experiment. The united ends of the bars should be ground together, so as to be kept in perfect contact, and preserved in this state by a powerful pressure during the time that they are magnetized. If this be done, we have no doubt that they will act on iron filings, and throw them into curves, as if they were a single bar, and will, by examination with a fine needle, exhibit the same regular distribution of magnetism which takes place in the most perfect magnet.

Upon the separation of the magnets thus united, Æpinus found that two poles were instantly developed in each half, but that the neutral points *c*, *c′*, fig. 18, were nearer the interior poles *s*, *n′*; or, what is the same thing, nearer the original neutral point C, than to *n* and *s′*. In the space of about a quarter of an hour, it had, however, advanced nearer to the middle points *c*, *c′*, and continued for some hours, and sometimes for days, to advance to these points, which it finally reached, thus completing the regular distribution of the two opposite magnetisms.

Some observations, but not very accurate ones, have been made on the division of magnets in the direction of their lengths. According to Dr Derham, the two portions sometimes have contrary, and sometimes the same poles, as when they were united. When one portion was much thinner than the other, the thinner portion had generally its poles reversed. This experiment does not possess much interest; for it can scarcely be doubted that, if we could divide a magnet in the direction of its length without any violence or concussion, each portion, whether thinner or thicker, would have, when separate, the same polarities as when combined. The experiment would be easily made by pressing two equal steel bars into close contact, magnetizing them in this state, and then separating them.

Analogy between magnets and unannealed glass.

A very remarkable analogy has been pointed out by Sir David Brewster between the preceding results and those which he has obtained with parallelopipeds of glass, which received the doubly refracting structure by being quickly cooled on all their surfaces from a state of red heat. This change is analogous to that of temper in a magnet; and the effect of it is to produce a certain development of positive and negative double refraction throughout the whole of the parallelopiped of glass. These phenomena will be minutely explained in our article on OPTICS; but we may state at present, that the structure of the glass modifies the action of the ether which it contains, just as the structure of the tempered steel keeps the two magnetisms in an uncombined state. This is shown in fig. 19, where AB is a thick plate of glass quickly cooled. The middle portion of it P has positive, and the external portions N, N, negative double refraction. The density of the ether in each of these portions varies according to a regular law; and the intensity of the doubly refracting force, at different points both of the positive and negative structures, is represented by a curve formed by the superposition of a straight line and a parabola. If we now cut the parellelopiped of glass into two halves, through the dotted line AB, fig. 19, each half will have the same structure as the whole, as shown in fig. 20; the parts that were formerly *positive* being now *negative*, and *vice versa;* and the intensity of the doubly refracting force in each half will be represented by the ordinates of a curve formed by the superposition of a straight line and a parabola. This fact is in perfect analogy with the magnetic one, and there are many other remarkable points of resemblance.

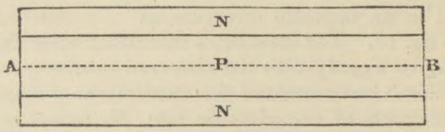

Fig. 19.

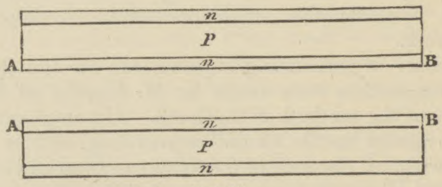

Fig. 20.

SECT. VIII.—*On the Magnetic Charge.*

The subject of magnetic charge, or the quantity of magnetism in a bar-magnet under a given attractive force, which may be termed intensity, has been investigated by Sir William Harris. He has shown, in the following interesting experiment, that this intensity is independent of the mass of the magnetized body, and, therefore, that magnetism, like electricity, is entirely confined to the surface.

Let AB be a cylinder, of soft iron 2 inches long, $\frac{1}{2}$ an inch in diameter, and $\frac{1}{10}$th of an inch thick. A solid cylinder of soft iron, *ab*, is made to fit into AB like one of the draw-tubes of a telescope, so that it can be pulled out to any point *c*, or altogether. Fix a magnet M, at a constant distance p, beneath AB, and bring the whole under the trial cylinder t of a magnetometer, in order to measure the quantity of magnetism induced upon the cylinder by the magnet M. The distances p and t being regulated by a divided scale, the intensity or force on t induced upon AB and ab, or in mass, was 10°. The cylinder ab being now pulled out to c, the intensity or force on t gradually declined; and when ab was pulled out as far as possible, the intensity was reduced, to 5° or $\frac{1}{2}$. When the interior cylinder was wholly removed the intensity became 10°, the same as when the two cylinders formed one. Hence it follows, that magnetism resides on the surface, a result confirmed by the fact that a hollow cylinder of tempered steel may be magnetized as powerfully as a solid cylinder of the same dimensions.[1] Sir W. Harris has found that the intensity or attractive force is as the quantity of magnetism, as in electricity.

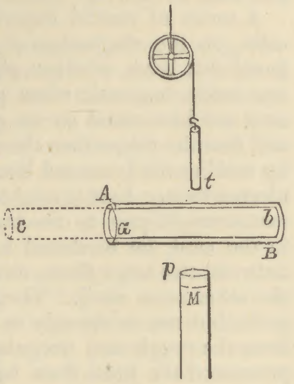

Fig. 21.

SECT. IX.—*On Magnetic Figures.*

Magnetic figures.

In our article on ELECTRICITY we have given an account of the beautiful clectrical figures discovered by M. Lichtenberg, and which form one of the most interesting popular experiments in that science. We are indebted to M. Haldat of Nancy for the analogous discovery of magnetic figures, which may be easily produced. For this purpose, he employed plates of steel from eight to twelve inches square, and from one-twentieth to one-eighth of an inch thick. The plates which he used were of that kind of steel which is used for the manufacture of cuirasses, so that it did not require to be tempered, being sufficiently hard to preserve the magnetism communicated to it. Figures of any kind may be traced on the surface of the steel plate, either by one magnet or by several combined; and the best form for this purpose is that in which the poles are rounded. In this way we may write upon a steel plate the name of a friend, or sketch a flower or a figure, with the extremity of a magnet. If it is a south pole that we use, all the traces which it makes will have north polar magnetism; and if we shake steel filings upon the plate out of a gauze bag, the filings will arrange themselves in the empty spaces between the lines traced by the pole of the magnet, and thus represent, in vacant steel, the name which has been written, or the flower or figure which has been sketched. "These figures," says M. Haldat, "have a perfect resemblance to those which are formed on the surface of non-magnetic plates,—viz., wood, card, glass, or paper, under which a magnet is placed. The resemblance between the two sorts of figures, when the magnets and the parts magnetized have the same form, is not only exact in the whole figure, but even in the smallest details. The filings collect at the parts where the magnetism is most intense, they arrange themselves in pencils and radii, and form the same curves which we have represented above (see fig. 1). These curves, and pencils, and rays, so similar at the two poles of the same magnet, have such a resemblance that they do not allow us to distinguish the two parts from one another."

M. Haldat likewise produced these curves by interposing between the tracing magnets and the steel plates solid non-magnetic bodies, such as cards, glass, and even metallic plates that are not ferruginous. This method of producing magnetism in the steel plate by induction gives the same figures; but, in order to be efficacious, the magnet must have its pole carried parallel to and at a small distance from the plate of steel, and must repeat its traces, in order that the magnetism may be sufficiently developed. For rectilineal figures, M. Haldat employed rules with grooves, which keep the motion and distance of the bar invariable; for curvilineal figures he interposed some thin and uniform plate, and varied the distinctness of the figures by varying the distance of the tracing pole of the magnet.

Magnetic figures.

In sifting the iron filings upon the steel plate, a gentle vibration of the plate, by tapping its edge with the ring of a small key, will assist the filings in taking their proper places; but we must avoid such vibrations as will produce regular acoustic figures, unless we wish, as M. Haldat found to be practicable, to unite the magnetic with the acoustic figures, which produces very interesting and varied forms.

M. Haldat found that the magnetic figures will continue for six months. In order to remove the magnetism which produces them, he recommended the heating of the plate upon red-hot charcoal, till it is brought to the straw-yellow temperature. In order to render the repolishing of the plate unnecessary, M. Haldat tinned it, and the temperature at which the tin melted, when it was required to efface the magnetism, indicated the necessary heat. M. Haldat employed also another method which is perhaps the best. He placed the steel plate upon a block of wood, and by repeated and violent blows of a wooden hammer he removed the magnetism of the plate, the figures gradually becoming weaker and weaker when the experiment was tried with it in different stages. The effect was often produced in three or four minutes.

As the figures traced on the steel are nothing more than magnets of different forms, and are surrounded on all sides with a substance capable of acquiring the magnetism which may be developed by communication, we might expect, as M. Haldat remarked, that this means of communication between the opposite poles of the magnets would bring them into a neutral state. This, however, is not the case; and the portion of the metal which surrounds the magnetic figure performs the part of the *armature* of a loadstone, and the magnetism is thus kept up. If the figure be a simple rectangle, like that of a bar-magnet, the state of the plate, examined with a small needle, is exactly the same as a bar-magnet, and the parts which surround this magnetic portion are in a neutral state, as if unconnected with the rectangular space; from which it follows that the magnetic virtue, which communicates itself so easily by influence, ceases to communicate itself between the continuous parts of a magnetizable body, of which one portion is magnetic, and the rest in a neutral state.

Improvements on M. Haldat's method.

In carrying into effect the preceding method of making magnetic figures, a very great difficulty must be experienced in recollecting the invisible traces made by the pole of the magnet, so as to complete a regular figure or drawing. When the figures are made *immediately*, as M. Haldat expressed it, that is, by the actual contact of the pole of the magnet, without any intermediate body, the best method would be to cover the plate of steel with the slightest coating of grease, and sift upon the surface, through a linen bag, some of the finest flour. The pole of the magnet, while tracing the figures on the steel, will remove the flour, and thus exhibit to the eye an accurate picture of what it has traced; and it will thus be easy to make the magnetic figures more distinct by repeating the traces with the magnet. The same thing may be done by putting an etching ground upon the steel plate, and tracing the figure as before. When the figure is completed, the coating of grease and flour, or the etching ground, must be removed previous to the application of the iron filings.

---

[1] *Rud. Mag.*, part iii. 61, 62.

Magnetism of Bodies not Ferruginous.

Magnetic figures.

When the figures are to be produced *mediately*, or by the intervention of a non-magnetic substance, such as paper, card, wood, or glass, a fine dust may in like manner be laid upon the surface; but when the interposed substance will receive the mark of a pencil or sharp point, it would be preferable to attach to the cylindrical pole of the tracing magnet a very short point of a non-magnetic substance, which would make a visible mark on the paper, card, or wood, without strewing any fine dust on their surfaces. By the use of such a point, indeed, we may dispense altogether with the interposed substance, and communicate the magnetism by induction to the steel plate, in the very same way as if it had been done by the intervention of a non-magnetic plate whose thickness is equal to the length of the short point or tracer affixed to the pole of the magnet.

The magnetic figures might be rendered permanent by covering the steel plate either with a gummy or balsamic solution, which will indurate by exposure to the air; or with a coating of some easily melted substance, which becomes fixed at ordinary temperatures. If we sift the iron filings on the steel plate when covered with such a fluid, the filings will take their magnetic position round the traced lines, and will become fixed by the induration or solidification of the fluid coating.

CHAP. III.—ON THE MAGNETISM OF BODIES NOT FERRUGINOUS.

SECT. I.—*On the Magnetism of Metals, Minerals, and other Bodies.*

Magnetism of metals, &c., not ferruginous.

Iron was long regarded as the only body endowed with the property of acting and of being acted upon as a magnet; and though other metals and substances have been found to possess the same property, and though all substances whatever were found by Coulomb to obey the power of a strong magnet, yet it is still a matter of doubt whether the magnetic effects thus produced are owing to a magnetism residing in the proper substance of the body, or are owing to a minute quantity of iron which enters into their composition.

Magnetism of nickel.

The most magnetic metal next to iron is *nickel*. It receives and retains communicated magnetism longer than any other metal, and needles of nickel have a distinct polarity. These properties have been found in nickel after it has been repeatedly purified, though some authors have stated that they could not detect this property in certain specimens. A very decisive and instructive experiment on the magnetic qualities of nickel was made by M. Biot.[1] He possessed a needle of nickel which had been purified by M. Thénard. It was 212 millimetres long, six broad, and 5·178 grains in weight. Having made a needle of steel of exactly the same dimensions, and which weighed 4·586 grains, he magnetized them both to saturation, and caused them to oscillate in the magnetic meridian. The nickel needle performed ten oscillations in eighty-seven seconds, and the steel one the same number in forty-five and a half seconds. As the shape of the needles was the same, the momenta of their directive forces were directly as their weights, and inversely as the squares of eighty-seven seconds and forty-five and a half seconds, that is, as 0·3088 to 1, that is, the directive force of the needle of nickel was *nearly one-third* of that of the steel needle. Now it is impossible to suppose that purified nickel could contain such a large proportion of iron as is necessary to produce such a degree of magnetic polarity, without its being easily recognised by the chemist; and M. Biot supposes that the magnetic power of the nickel might have been still further increased by the means which are used to modify the coercive power of steel and iron.

Magnetism of Bodies not Ferruginous.

Brass.

A series of careful experiments were made by M. Cavallo, on the magnetism of *brass* when hammered. He found that brass, whether old or new, British or foreign, was made magnetic when placed between two pieces of card and hammered on an anvil with a common hammer; and that the magnetism thus imparted was always removed by making the brass red hot, and could again be communicated to it. Lest it might be supposed that ferruginous matter might pass to the brass through rents or openings in the card, he hardened a piece of brass by beating it between two large flints, using one piece as a hammer, and the other as an anvil. The hammered brass became magnetic, but not so strongly as before; which arose probably from the rough and irregular surfaces of the flints, which prevented the brass from being hardened as uniformly as it was with the steel hammer. The flints, before and after the experiment, did not possess the slightest magnetism.

The degree of magnetism communicated to brass by hammering is vaguely stated by Cavallo to have been such "as to attract either pole of the needle from about a quarter of an inch distance." The following are the conclusions which M. Cavallo has drawn from these and other experiments:—

"1*st*, That most brass becomes magnetic by hammering, and loses its magnetism by annealing or softening in the fire, or at least its magnetism is so far weakened by it, as afterwards to be only discoverable when set to float on quicksilver.

"2*d*, The acquired magnetism is not owing to particles of iron or steel imparted to the brass by the tools employed, or naturally mixed with the brass.

"3*d*, Those pieces of brass which have that property, retain it without any diminution after a great number of repeated trials, viz., after having been repeatedly hardened and softened.

"4*th*, A large piece of brass has generally a magnetic power somewhat stronger than a smaller piece, and the flat surface of the piece draws the needle more forcibly than the edge or corner of it.

"5*th*, If only one end of a large piece of brass be hammered, then that end alone will disturb the magnetic needle, and not the rest.

"6*th*, The magnetic power which brass acquires by hammering has a certain limit, beyond which it cannot be increased by farther hammering. This limit is various in pieces of brass of different thicknesses, and likewise of different qualities.

"7*th*, Though there are some pieces of brass which have not the power of being rendered magnetic by hammering, yet all the pieces of magnetic brass that I have tried lose their magnetism, so as no longer to affect the needle, by being made red hot, excepting indeed when some pieces of iron are concealed in them, which sometimes occurs; but in this case the piece of brass, after having been made red hot and cooled, will attract the needle more forcibly with one part of its surface than with the rest of it; and hence, by turning the piece of brass about, and presenting every part of it successively to the suspended magnetic needle, one may easily discover in what part of it the iron is lodged.

"8*th*, In the course of my experiments on the magnetism of brass, I have twice observed the following remarkable circumstance:—A piece of brass which had the property of becoming magnetic by hammering, and of losing the magnetism by softening, having been left in the fire till it was partially melted, I found upon trial that it had lost the property of becoming magnetic by hammering; but having

---

[1] *Traité de Physique*, tom. iii., p. 126.

Magnetism of Bodies not Ferruginous.

been afterwards fairly fused in a crucible, it thereby acquired the property it had originally, viz., that of becoming magnetic by hammering.

"9*th*, I have likewise often observed, that a long continuance of a fire so strong as to be little short of melting hot, generally diminishes, and sometimes quite destroys, the property of becoming magnetic in brass. At the same time the texture of the metal is considerably altered, becoming what some workmen call *rotten*. From this it appears, that the property of becoming magnetic in brass by hammering, is rather owing to some particular configuration of its parts, than to the admixture of any iron; which is confirmed still farther by observing that Dutch plate brass (which is made, not by melting the copper, but by keeping it in a strong degree of heat whilst surrounded by *lapis calaminaris*) also possesses that property; at least all the pieces of it which I have tried have that property. From these observations it follows, that when brass is to be used for the construction of instruments wherein a magnetic needle is concerned, as dipping needles, variation compasses, &c., &c., the brass should be either left quite soft, or it should be chosen of such a sort as will not be made magnetic by hammering, which sort, however, does not occur very frequently."

These judicious suggestions of M. Cavallo respecting the condition of the brass parts of azimuth compasses were not attended to as they ought, and we have no doubt that various grave errors have arisen from their neglect. Many examples have since occurred in which the errors were detected; and it is now the invariable practice of well-informed instrument-makers to reject hammered brass bowls for compasses, and to use those which are cast and turned for the purpose.

Magnetism of cobalt, zinc, &c.

M. Cavallo and others have observed, that cobalt, zinc, copper, and bismuth, as well as their ores, are attracted by the magnet, and antimony when gently heated. Minerals which are not metallic are almost all acted upon by the magnet, particularly where they have experienced the action of fire. The pure earths, and particularly silex, are found to have the same property. Among minerals, the following table shows those which are attracted and those which are not attracted by the magnet; but we place little faith in their accuracy.

Of gems.

Minerals not attracted.	Minerals attracted.
Diamond.	Oriental ruby.
Pellucid crystals.	Chrysolite.
Amethyst.	Tourmaline.
Topaz.	Emerald.
Calcedony, and other crystals whose colouring matter is expelled by heat.	Garnet.
	Several micas containing iron.

Of mica.

Some accurate experiments were made on mica by M. Biot. The chemical composition and optical structure of different varieties of this mineral vary greatly. M. Biot examined particularly mica from Siberia and mica from Zinwald in Bohemia. Though both were highly pellucid, yet chemical reagents indicated in each the existence of oxide of iron. In the Bohemian mica it was greatest, and, according to an accurate analysis by Vauquelin, amounted to 20 per cent. Before the Siberian mica was analysed, M. Biot tried their magnetic properties. He cut out of each, thin rectangular plates of the same form, which he subdivided into smaller similar pieces, and having united them in a bundle, he suspended each bundle by a silk fibre, and caused each bundle to oscillate in succession between the poles of two strong magnets. The bundle of Zinwald mica performed 12 oscillations in 55 seconds, and that of the Siberian mica only 7 in the same time. Hence the magnetic powers of the two micas were as 6·8 to 20, the ratio of 49 and 14 to the squares of the number of oscillations. If the oxide of iron, then, be the cause of their magnetic virtue, it should exist in the above proportions of 6·8 to 20; and as it was found to be 20 per cent. in the Zinwald mica, it ought to be 6·8 in the Siberian. It is very remarkable that the result of Vauquelin's analysis gave exactly this percentage of the oxide of iron, though it was not known to M. Biot till his experiment had been made.

Magnetism of Bodies not Ferruginous.

Magnetism of combined metals.

The existence of magnetism in brass, while there appeared not the least trace of it either in the copper or zinc of which it is composed, led philosophers to investigate the effects produced by the union of different metals, or by their combination with other substances. *Iron* itself is a simple chemical body. *Steel* is a combination of iron and carbon. The *loadstone* is a combination of iron and oxygen; and as no magnetism was found either in carbon or oxygen, philosophers were naturally led to believe, as M. Pouillet has remarked, that the magnetic fluid resides in the iron, and that it is carried with the atoms of that metal into all the chemical combinations which they form. They therefore expected to find magnetic properties more or less developed in all ferruginous bodies, whether the iron was an accidental or an essential ingredient; and indeed cast iron, plumbago, and the oxides and sulphurets of iron, exert a sensible action on the magnetic needle.

Anti-magnetic bodies.

These views, however, are not in unison with facts which seem to have been well ascertained. Dr Matthew Young found, that the smallest admixture of antimony was capable of destroying the polarity of iron; and M. Seebeck stated, that an alloy of one part of iron and four parts of antimony was so completely destitute of magnetic action, that, even when it was put into rotation, it exerted no power over the magnetic needle. The magnetic qualities of nickel also are destroyed by a mixture with it of other metals. Chenevix found that a very small proportion of arsenic deprived a mass of nickel which had previously exhibited a strong magnetic power, of the whole of its magnetism; and Dr Seebeck found that an alloy of two parts of copper with one of nickel was entirely devoid of magnetism, and on this account he recommended it as well suited for the manufacture of compass boxes. On the other hand, Mr Hatchet ascertained, that when a large proportion of *carbon*, or *sulphur*, or *phosphorus*, was combined with iron, the iron was enabled fully to receive and retain its magnetic properties; but he at the same time found that there was a limit beyond which an excess of any of these three substances rendered the compound wholly incapable of receiving magnetism.

Animal and vegetable substances, after combination, are said to be attracted by the magnet. The flesh, and particularly blood, are acted upon more powerfully than other parts, and bone less powerfully. Burned vegetables have the same property, and also soot and atmospheric dust; and M. Cavallo maintained that brisk chemical effervescence acted upon the magnetic needle.

Sect. II.—*Account of the Experiments of Coulomb, Becquerel, Arago, and Seebeck, on the Existence of Universal Magnetism.*

Universal magnetism.

These various experiments on the magnetic power of so many classes of bodies, differing essentially in their composition, and in many of which it could not be reasonably supposed that iron existed, led some philosophers to believe that almost all substances gave indications of magnetism. M. Cavallo announced this opinion, but Mr Bennet questioned the accuracy of the experiments, and ascribed the movements observed in the needle to the agitation of the air in the receiver, arising from changes of temperature produced by the proximity of the observer's body, or from other causes.

It was not therefore till 1802, that the supposition of

Magnetism of Bodies not Ferruginous.

Coulomb's experiments.

universal magnetism was put to the test of rigorous experiment. The apparatus which Coulomb employed for this purpose is shown in fig. 22, where AA is a glass receiver perforated at its top, and having a tube A′B, with a cork B, which could be raised and lowered with facility. Through this cork passed a rod tt' of wood or metal, to which was attached a silk fibre, which suspended a ring of very fine paper, on which the small needle *ns* (about the third of an inch long and $\frac{1}{50}$th thick) was placed. The receiver was then placed so as to inclose the opposite poles N, S of the powerful magnets M, M, each formed of four bars of steel tempered to a white heat. Each bar was 17 inches long, $\frac{3}{8}$ths of an inch wide, and $\frac{1}{6}$th of an inch thick; each bundle of four bars being $1\frac{3}{8}$th of an inch wide, and $\frac{1}{3}$d of an inch thick. The distance N, S, of their poles was $\frac{8}{10}$ths of an inch. In making the experiments, the rod tt' was turned till the needle *ns* was removed from the influence of the magnets; and after the number of its oscillations was observed, the rod tt' was turned till the needle descended between the poles N, S of the magnets, when the number of oscillations of the needle was again counted, or the time in which a given number of oscillations was performed. If the needle performed the same number of oscillations in the same time, whether it oscillated between the poles N, S, or beyond their influence, it is obvious that the magnets exercised no power over them; but this was never the case, and Coulomb asserted that all substances whatever, when formed into small needles, turned themselves in the direction of the poles N, S, and after a few oscillations, finally settled in that position. When these bodies were moved a very little way out of their position of equilibrium, they immediately began to oscillate round it, the oscillations being always performed more rapidly in the presence of the magnets than when they were removed out of their influence. Gold, silver, glass, wood, and all substances, whether organic or inorganic, thus obeyed the power of the magnets. Hence it was natural to conclude, either that all bodies are susceptible of magnetism, or that they contain minute quantities of iron, or other magnetic metals, which give them that susceptibility. M. Biot did not consider this alternative so inevitable as it appears, and threw out the conjecture, that the action may not be magnetic, but may be owing to some small force similar or analogous to the electrical forces developed by the simple contact of heterogeneous bodies. This no doubt might be, if there was any contact; but, in the absence of any other reasons, such as later experiments have afforded, for ascribing the observed effects to another cause, we cannot but think that it was even then the wiser alternative to give a preference to that opinion which ascribes the phenomenon to the existence in all bodies of a slight susceptibility to magnetic action.

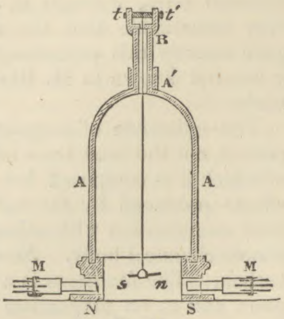

Fig. 22.

The results of experiments made by Coulomb on the comparative magnetic susceptibilities of cylindrical needles of gold, silver, lead, copper, and tin, which had been purified with the greatest care by MM. Sage and Guyton, we have already given in our history of magnetism. M. Coulomb made a number of experiments on the effects experienced by needles of white wax containing different proportions of iron filings, and he came to the conclusion that the intensities of the action which they experienced when oscillating between two magnets, was proportional to the absolute quantities of iron which they contained, the distribution and chemical state of the ferruginous particles being the same.

Magnetism of Bodies not Ferruginous.

Since the time of Coulomb, methods different from his have been employed in developing magnetism in all bodies whatever. In order to detect small quantities of iron in minerals, M. Haüy employed the process of what he calls *double magnetism.* For this purpose he placed a small bar-magnet in the direction of the needle, and in the same horizontal plane, the two similar poles being placed towards each other. The magnet being now brought slowly towards the needle, the latter deviates from the direction of the magnetic meridian, and takes a position perpendicular to it; an effect arising from the combined action of the poles of the magnet and the earth upon the magnetism of the needle. In this position, *a very feeble magnetic action* is sufficient to make the needle turn round and place its south pole opposite the north pole of the needle.

When the magnet is above the plane of the needle, and their opposite poles placed near each other, the needle does not change its direction while the point of suspension is beyond the bar and at a suitable distance; but it is not so when the distance changes, for it tends continually to place itself perpendicular to the line of the poles.

Researches of M. Becquerel.

This important subject was investigated by M. Becquerel, who obtained the following results.[1] His bar-magnet consisted of six united bars, each 8 decimetres long and 2 centimetres broad. The needle was place at different heights within and without the bar, and he sought to determine for each height the horizontal distance from the point of suspension (which is always in the line of the poles) to the nearest extremity of the needle, in order that its direction might be perpendicular to that line. The results were as follows:—

Vertical Distances from the centre of suspension to the Bar. Millimetres.	Horizontal distances of the centre of suspension to the extremity, in order that the needle might take a perpendicular position. Millimetres.
100	60 within.
150	55
200	46
250	23
300	12
350	45 without.
400	82

Hence it appears, that when the centre of suspension is above the bar, the perpendicular position is obtained by increasing the vertical and diminishing the horizontal distance; and that both these distances are increased while the centre of suspension is below the bar; and the direction of the deviation depends on accidental causes, and is often determined by the simple motion of the apparatus.

When M. Becquerel substituted for his magnetic needle a needle of soft iron, the results were exactly the same, differing only in their intensity. We come now to the original part of M. Becquerel's inquiry. Instead of a needle he used a small paper case filled with *deutoxide of iron,* or a mixture of deutoxide and tritoxide. With the former the effects were the same as with the steel needle; but it was different with the latter, in which one part of deutoxide was mixed with thirty parts of tritoxide.

If the centre of suspension be placed as near as possible to the north pole of the bar-magnet, and in the line of the poles, the paper case will take immediately a direction perpendicular to this line, instead of one coincident with it, as a soft-iron needle would have done. If we put it out of this direction, it will return to it by a series of oscillations, whose velocity depends on the quantity of the deutoxide. From this it follows, that *all the south-*

---

[1] *Traité Exp. de l'Electricité, &c.,* tom. ii., p. 387.

Magnetism of Bodies not Ferruginous.

polar magnetism of the paper case is situated on the side of it next the bar-magnet, while the north polar magnetism is on the other side, as may be exhibited by carrying a small magnetic needle along the paper case. Such a distribution of magnetism is impossible in soft iron or tempered steel.

If the centre of suspension be above the bar, the paper case will deviate from the position which it had at first, and tend to place itself in the direction of the line of the poles; an effect quite opposite to that produced by a steel or iron needle. The following were the experimental results:—

Vertical Distances of the Centre of Suspension from the Bar.	Horizontal Distances of the same Centre to one of the Extremities of the Bar.	Deviations of the Paper Case from the Direction perpendicular to the Line of the Poles.
10 millimetres	5	24°
	10	44

	15	73
	20	77
	30	32
30 millimetres	5	70
	20	76
	30	82

The *transverse magnetism* acquired by the paper case is permanent for some time, however small may be the proportion of the deutoxide which it contains.

M. Becquerel next filled the paper case with very pure tritoxide, obtained by calcining nitrate of iron. The effect was much weaker than before. When the point of suspension was very near one of the extremities of the bar, the paper case still placed itself in a position perpendicular to the line of the poles; but if this point was placed above or below the bar, changing at the same time the vertical distance, the paper case deviated from its primitive direction, without, however, taking a direction perpendicular to that which it commonly takes when the centre of suspension is very near the extremity. It might be possible, M. Becquerel thinks, to attain the perpendicular direction by employing much stronger magnets. The following were the experimental results:—

Vertical Distances from the Point of Suspension to the Bar.	Horizontal Distances of the same Point from the end of the Bar.	Deviations from the Direction perpendicular to the Line of the Poles.
	Without the Bar.	
5 millimetres	5	25°

	15	30
	20	45
	25	50

Whenever the tritoxide contains the smallest quantity of the deutoxide, the velocity of the oscillations increases very powerfully. If, for example, we take *two* paper cases, one filled with tritoxide, and the other with tritoxide mixed with one-thirtieth of the deutoxide, the first will perform twelve oscillations in thirty seconds round a direction perpendicular to the line of the poles, while the other will execute twenty-five in the same time. Hence we may by this means readily determine the quantity of the deutoxide of iron contained in the tritoxide.

Magnetism of Bodies not Ferruginous.

With needles of wood, &c.

M. Becquerel next employed needles of wood, gum-lac, and other substances, which have still a feebler magnetism than the tritoxide of iron. He placed a needle of white wood, *ns*, four centimetres long and two millimetres in diameter, above the interval between the opposite poles of two bar-magnets, as in fig. 22, the distance between N and S being three or four millimetres. The point of suspension was as near as possible to NS. The needle placed itself perpendicular to the line of the poles NS, in place of the position observed by Coulomb coincident with NS. It comports itself therefore like the mixture of deutoxide and tritoxide of iron, or like the tritoxide alone. But if we separate gradually the extremities N, S of the bars, the wooden needle will place itself in the line NS joining the poles, as shown in the figure. The deviations were as follows:—

Distances of N, S.	Deviations of the Wooden Needle from the perpendicular position.
3 or 4 millimetres	0°
10 ...	18
20 ...	36
30 ...	56

When the bars are very close, and the needle in the perpendicular position, if we draw it out of this position, and keep it some instants in the direction of this line, it will remain there; but the smallest motion will cause it to return into its primitive direction, which it takes in preference to any other.

If we use only one bar-magnet, and place the wooden needle precisely opposite one of its poles, and as near as possible to the end of the bar, it will still direct itself perpendicularly to it; but if, while the point of suspension remains always in this line, we advance it within the bar, the needle will deviate from its direction, without, however, reaching the position of 90°, as will be seen from the following results:—

Distances of the Centre of Suspension from the Extremity of the Bar.	Deviations of the Wooden Needle.
5 millimetres	12°
10 ...	18

Beyond ten millimetres the deviations increase insensibly and irregularly, so that they cannot be measured.

General conclusion.

From these interesting experiments, M. Becquerel concludes that the magnetic effects produced by a strong bar-magnet upon a magnetic needle, or one of soft iron, differ essentially from those which take place in all bodies where the magnetism is very weak. In the former, whatever be their positions and directions, the magnetism is always distributed in the direction of their length, to the exclusion of every other direction; whereas in the tritoxide of iron, wood, and gum-lac, it is distributed in a direction which depends on the distance of the body from the poles of the magnet, so that the distribution varies with the direction which the magnet causes these needles to take, in virtue of the action which it exercises over them.

Discoveries of M. Arago.

The universal prevalence of magnetism in all bodies whatever has been established by a beautiful discovery of M. Arago. This distinguished philosopher conceived the idea of studying the oscillations of a magnetic needle when placed above or near any body whatever. Having suspended a magnetic needle above metal, or even water, and caused it to deviate a certain number of degrees from its position, it began, when left to itself, to oscillate in arcs of less amplitude, as if it had been placed in a resisting medium; and, what was peculiarly curious in these experiments, this diminution in the amplitude of the oscillations did not alter the number of oscillations which were performed in a given time. The following were some of M. Arago's

Magnetism of Bodies not Ferruginous.

experiments with *water*, *ice*, and *glass*, the semiamplitude of the oscillations being at the instant 43°.

The distance of the water from the needle was	0·65 millimetres.
The amplitude lost 10° in	30 oscillations.
When the distance was	52·2 millimetres.
A loss of 10° of amplitude required	60 oscillations.

That is, the number of oscillations required to diminish the amplitude 10° was twice as great when the distance of the needle from the water was 52·2 millimetres, as when it was 0·65.

By placing the same needle upon ice M. Arago obtained the following results :—

Distance of the Needle from the Ice. Millimetres.	Diminution of the Amplitude.	Number of Oscillations by which this diminution was effected.
0·70	From 53° to 43°	26 oscillations.
1·26	From 53 to 43	34 ...
30·50	From 53 to 43	56 ...
52·20	From 53 to 43	60 ...

By placing another needle near a plate of crown glass, he obtained the following results :—

Millimetres.		
0·91	From 90° to 41°	122 oscillations.
0·99	From 90 to 41	180 ...
3·04	From 90 to 41	208 ...
4·01	From 90 to 41	221 ...

Plates of metal afforded M. Arago similar results ; but he nevertheless observed that those metals which act with more energy than glass, wood, &c., have a mode of action different from that of these substances. From all these results, it is manifest that all bodies, when placed near a magnetic needle in a state of oscillation, exercise over it an action, the effect of which is to diminish the amplitude of its oscillations, without altering their number ; and hence the doctrine of the universal prevalence of magnetism in all bodies derives a new confirmation.

When Dr Seebeck of Berlin heard of the discovery of M. Arago, he made a magnetic needle two and an eighth inches long oscillate at a distance of three lines above plates of various bodies, and counted the number of oscillations which were required in each case to reduce the amplitude from 45° to 10°.

Substances employed.	Thickness of the Plates.	Number of Oscillations of the Needle.
Marble	— line	116 oscillations.
Mercury	2·0 ...	112 ...
Bismuth	2·0 ...	106 ...
Platina	0·4 ...	94 ...
Antimony	2 0 ...	90 ...
Lead	0·75 ...	89 ...
Gold	0·2 ...	89 ...
Zinc	0·5 ...	71 ...
Tin	1·0 ...	68 ...
Brass	2·0 ...	62 ...
Copper	0·3 ...	62 ...
Silver	0·3 ...	55 ...
Iron	0·4 ...	6 ...

Dr Seebeck found, that in alloying magnetic with non-magnetic substances, he formed *compounds which exercised no action on the magnetic needle.* The alloys which had particularly this singular property were those consisting of four parts of antimony and one of iron, or two parts of copper and one of nickel. In these cases the magnetism of the two ingredients must have been neutralized by their opposite actions.

SECT. III.—*On Diamagnetism.*

The doctrine of universal magnetism, as explained in the two preceding sections, has not stood the test of recent and more profound investigations. The fine researches of Dr Faraday have thrown a new light upon the subject, and brought to view a series of remarkable phenomena of which we shall endeavour to give a brief account.

In the year 1845 Dr Faraday discovered, that when magnetic currents, or, as he expresses it, lines of magnetic force, pass through certain bodies, they communicate to these bodies a certain magnetic condition, which, in transparent bodies, is analogous to rotatory double refraction and polarization, and which in other bodies is the reverse of that which takes place on iron, nickel, and some other metals.

Magnetism of Bodies not Ferruginous.

If a parallelopiped, NS*ns*, of heavy flint glass, 2 inches square and $\frac{1}{2}$ an inch thick, and having no action on polarized light, is placed, as in the figure, on the poles N, S, of a powerful electro-magnet NCS, and a strong galvanic current passed through it in the direction of *sn*, the glass will neither be attracted nor repelled, but is found to have received, while the current is passing through it, such a structure, resembling that of quartz and certain fluids, as to *turn the plane of a polarized ray* in the same direction as the current. If the polarized ray is transmitted through the upper and under faces G, H, no effect whatever is produced. The rotation of the plane of polarization is from *left to right* when the ray enters the face *s*N and the observer looks into the face *n*S, and from *right to left* when the ray enters *n*S and the observer looks into *s*N. This is a very remarkable fact, as the direction of rotation is the same in rock-crystal and other bodies through whatever side the light enters.

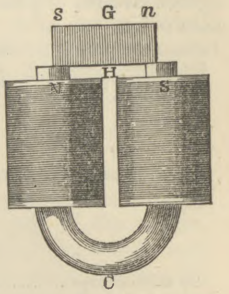

Fig. 23.

The intensity of the rotatory force depends upon the strength of the galvanic current, and upon the length of the piece of glass. When the ray, by reflections at *n* and *s*, was made to pass *three* or *five* times through the length *ns* of the glass, the effect was increased *three* or *five* times, just as in rock-crystal it is increased by increasing the thickness of the plate.

M. Bertin found that this electro-magnetical polarization as it has been called, or magne-crystallization as Dr Tyndall calls it, as produced in *boro-silicate of lead* (Faraday's flint glass), and the *sulphuret of carbon*, does not vary in intensity, by a variation, within very considerable limits, of the electro-magnetic force. He found that the most energetic of the fluids which exhibited the rotatory structure were *bichloride of tin, sulphuret of carbon, olive oil, alcohol,* and *water ;* the sulphuret of carbon having *three* times the force of water.

In studying this subject, M. Matthiessen of Altona obtained the following results :—

1. The rotatory force diminished as the distance of the poles N, S was increased, the diminution being more rapid when the glass was thinner.

2. The effect was not a maximum when the glass was in absolute contact with the poles of the magnet ; the magnetism probably passing freely through the glass without producing rotation.

3. When the parallelopiped *ns*NS consisted of six similar plates, the effect was diminished about $\frac{2}{13}$ths, but there was no diminution when the plates were cemented by Canada balsam.

4. With 50 elements of Bunsen's pile, producing such a degree of magnetism that one of the vertical poles of the magnet raised 25 kilogrammes, M. Matthiessen obtained the following results :—

	Thickness in Millimetres.	Angle of Rotation.
Silicate seplombique	15	20
Silicate quadroplombique	10	18
Silico-aluminate of lead	10	16
Borate triplombique	17	16
Red realgar	12	11
Borate of bismuth	14	11
Borate of lead, neutral	24	10

Magnetism of Bodies not Ferruginous.

	Thickness in Millimetres.	Angle of Rotation.
Silicate of lead, neutral	30	10
Glass of antimony	27	9
Borosilicate of lead	26	9
Rock-salt	26	6

From a series of interesting experiments, M. Bertin recently obtained the following values of the rotatory force, which he calls the *coefficients of magnetic polarization.* In all the experiments, the thickness of the body and the distance of the poles of the magnet were the same:—

	Coefficient.
Faraday's flint-glass	1·00
Guinand's do.	0·87
Matthiessen's do	0·83
Common do.	0·53
Bichloride of tin	0·77
Sulphuret of carbon	0 74
Protochloride of phosphorus	0·51
Chloride of zinc, dissolved	0·55
Chloride of calcium, dissolved	0·45
Water	0·25
Alcohol, ordinary, of 36 Beaumé	0·18
Ether	0·15

The remarkable property of magnetic polarization will, no doubt, be found in many other bodies both solid and fluid; but it has not yet been detected in Iceland spar, rock-crystal, or any doubly-refracting substances. It will be found doubtless in diamond, garnet, and other minerals that do not possess double refraction.

But though a crystalline structure is not produced in doubly-refracting bodies, they are influenced by the magnetic current in a different way, like a large class of bodies to which the name of diamagnetic has been given.

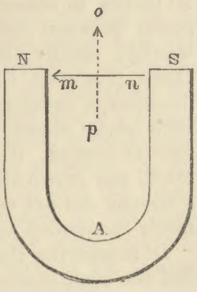

Fig. 24.

If N, S are the poles of a very powerful electro-magnet NAS, and if bodies such as those examined by Coulomb are placed between these poles, they will take the position *mn;* but there is another class of bodies, such as bismuth, which if placed in the *magnetic field* NS, will not place themselves *axially* like *mn*, but equatorially like *op*, even though they had previously the position *mn.* If the diamagnetic body is nearer N than S, or nearer S than N, that is, out of the centre C, then on pointing equatorially it is apparently repelled, and this, too, by both poles; so that it was inferred by Dr Faraday we have here magnetic repulsion with *polarity* or *directive power.*

Among the numerous diamagnetic bodies which take the equatorial position *op*, we find *wood, animal fibre,* and common vegetable matter; and it has been remarked by Sir W. Harris, "that if a man could be suspended with sufficient delicacy in the magnetic field between the poles of a powerful magnet, he would point equatorially (like *op*) and be repelled by both poles; for all the substances constituting the human frame have this property."

The following is a list of metals which, according to Dr Faraday, when placed in the magnetic field NS, take the *axial* position *mn*:—

Magnetic Metals.
Iron
Nickel
Cobalt
Manganese
Chromium

Magnetic Metals.
Cerium
Titanium
Palladium
Platinum
Osmium.

The following is a list of metals which, according to Dr Faraday, when placed in the magnetic field, take the *equatorial* position *op*:—

Diamagnetic Metals.
Bismuth
Antimony
Zinc
Tin
Cadmium
Sodium

Diamagnetic Metals.
Mercury
Lead
Silver
Copper
Gold

Diamagnetic Metals.
Arsenic
Uranium
Rhodium
Iridium
Tungsten.

The repulsion of bismuth and antimony was observed in 1778 by Brugmans, by M. Lebaillif in 1827, and by other philosophers; but these observations do not affect the entire originality of Dr Faraday's discoveries. M. Becquerel, who noticed the equatorial position of certain substances, supposed it to be the result of ordinary magnetic action, the bodies being magnetized transversely, or across their length, an explanation entirely disproved by the researches of Dr Faraday, which established the existence of a new magnetic condition of matter hitherto unsuspected.

This subject has been treated with great ability by Professor Tyndall, in the *Philosophical Transactions* for 1854 and 1856. Professor W. Weber, in opposition to the received opinion that metals such as bismuth had no polarity or directive power, had proved experimentally the existence of a reverse polarity in diamagnetic bodies. M. von Feilitzsch denied the validity of this inference, and ascribed the observed effect to ordinary induction. By means of an apparatus constructed by Professor Weber, Professor Tyndall has, by aid of able experiments, completely established the doctrine of a duality of action, that is, of a repulsive and a directive power residing in diamagnetic bodies.

In submitting to experiment liquid magnets, or liquid diamagnets (metallic solutions), Professor Tyndall has clearly shown that the former exhibit a polar action the reverse of that exhibited by the latter; and in a subsequent paper[1] he has pointed out the relation of diamagnetic polarity to magnecrystallic action.

Development of Magnetism in all Bodies by Rotation.

CHAP. IV.—ON THE DEVELOPMENT OF MAGNETISM IN ALL BODIES BY ROTATION.

M. Arago's experiments.

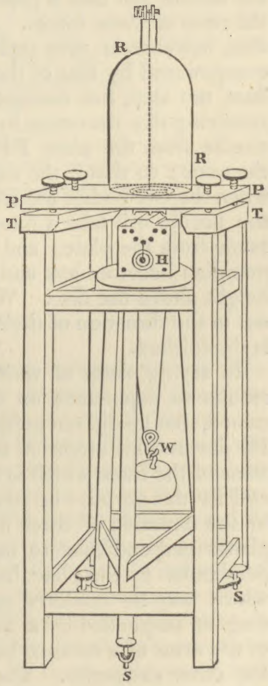

Fig. 25.

When M. Arago was engaged in the experiments described in the preceding chapter, the idea occurred to him of trying if the magnetic needle would be dragged along by the rotatory plates which had the power of diminishing the amplitude of its oscillation. This happy conjecture was immediately confirmed by experiment, and one of the most beautiful discoveries added to the science of magnetism.

The apparatus which he used for this purpose is shown in fig. 25, where H is a clock made of copper, with the exception of two or three pivots, which are of steel. It is supported on a tripod stand, which can be levelled by screws S, S, at the end of its three feet; and the object of it is to give a rapid rotatory motion by a vertical axis, on which is fitted a piece *abc*, fig. 26, with three branches, upon which the revolving discs are to be placed. These discs are perforated at their centre by a small hole which receives the prolongation of the axis of rotation, and they are kept upon the branches *a*, *b*, *c*, by the pressure of a

---

[1] *Philosophical Magazine,* February 7, 1856.

Development of Magnetism in all Bodies by Rotation.

screw. Wings *w*, *w*, *w* (fig. 26), which can be inclined at any angle, are applied for the purpose of retarding the velocity of the discs. A plate PP, with an opening in its centre a little larger than the diameter of the discs, rests upon the table TT; and a sheet of paper *ff*, shown in fig. 27 (which is an enlarged view of that part of the apparatus), is pasted to the lower face of PP.

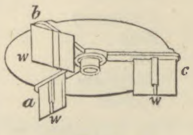

Fig. 26.

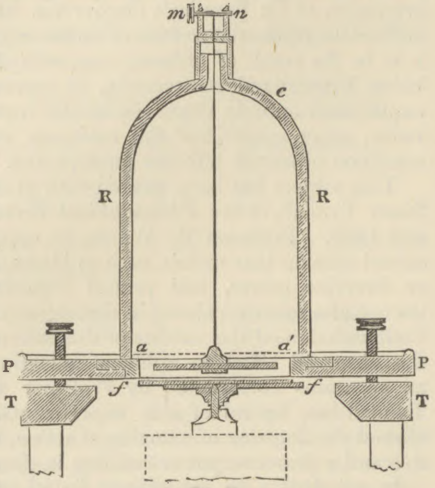

Fig. 27.

A glass receiver RR rests upon the upper face of PP, and within it is suspended the magnetic needle *aa'*, by a fibre of silk attached to the axis and button *mn*, by which the needle can be raised or depressed. A weight W gives motion to the clock, and a hand indicates upon the dial-plate the number of revolutions performed by the disc in a given time.

When a disc of copper was placed on the support *abc*, fig. 26, as shown at PP, fig. 27, and the copper made to revolve beneath the needle *aa'*, with the sheet of paper *ff* intervening, the needle *aa'* is drawn out of the magnetic meridian the instant that the copper begins to revolve, and with a degree of force proportional to the velocity of rotation. As the force with which the needle is dragged from its place is opposed to the magnetic action of the earth, which tends to keep the needle in the magnetic meridian, the needle will take a position of equilibrium depending on the ratio of these forces. When the motion of the copper disc, however, is very rapid, the magnetism of the earth is overpowered by that of the revolving plate, and the needle does not stop, but continues to turn. The action of the revolving disc decreases in proportion as the distance of the needle from the plate PP is increased, the velocity being the same; so that if the motion of the needle be continuous when the two bodies are separated only by a sheet of paper, the needle will take a fixed position by increasing its distance from the plate; and its deviation from the magnetic meridian becomes less and less as it is removed to a greater height above the disc. When the plates have portions cut out in the direction of their radii, their action on the needle is diminished.

In trying plates of various metals, M. Arago found the results so dependent on the alloy which the metals contained, that he did not publish the results which he obtained. He devoted his attention to the determination of the directions of the force which is developed in the revolving discs, and for this purpose he sought the components of this force in the direction of three lines parallel to three co-ordinate planes perpendicular to each other. The *component* perpendicular to the plate he found to be a repulsive force, which may be rendered sensible by means of a very long magnet suspended by a thread vertically to the extremity of the arms of a balance kept in equilibrium by a weight at the other extremity. The moment that the plate begins to revolve, the magnet is repelled, and the beam of the balance inclines to the other side. The *second* component is horizontal and perpendicular to a vertical plane which contains the radius abutting against the projection of the pole of the needle. This is the force which gives a motion of rotation to the needle, and it acts in the direction of a tangent to the circle. The *third* component is parallel to the radius which abuts against the projection of the pole of the needle. It may be determined with a dipping needle placed vertically, so that its axis of rotation is continued in a plane perpendicular to one of the radii of the disc. A similar needle placed at the centre of the disc experiences no action. There is also a second point, nearer the margin than the centre, where a needle experiences no change in its position; but between these points the lower pole is constantly attracted towards the centre, while it is repelled beyond that point.

Development of Magnetism in all Bodies by Rotation.

Experiments of Messrs Babbage and Herschel.

No sooner were M. Arago's experiments announced to the Institute, which was done at the sitting of the 7th March 1825, than philosophers in every part of Europe repeated them, and succeeded in adding several important facts to those discovered by M. Arago. MM. Babbage, Herschel, Barlow, Nobili, Baccelli, Christie, and MM. Prevost and Colladon, took a prominent part in these researches. The results obtained by Messrs Babbage and Herschel were the most important, and the experiments were made in a manner different from those of M. Arago. A horse-shoe magnet, which lifted twenty pounds, was made to revolve rapidly round its axis of symmetry, placed vertically, with its poles uppermost. A circular disc of copper, 6 inches in diameter and $\frac{1}{20}$th of an inch thick, was suspended above the revolving magnet. As soon as the rotation of the magnet commenced, the copper began to turn in the same direction, at first slowly, but afterwards with an increasing velocity. When the magnet was made to turn in the opposite direction, the disc of copper changed the direction of its motion also, and exhibited the same phenomena. Metallic plates, 10 inches in diameter and half an inch thick, when interposed between the magnet and the copper disc, did not sensibly modify the results, as M. Arago had observed. Glass produced no effect, but a sheet of tin-plate iron diminished greatly the influence of the magnet, while two such plates almost destroyed it. They also found that a disc of copper, 10 inches in diameter, and half an inch thick, and revolving with a velocity of seven revolutions in a second, did not communicate any motion to a similar disc freely suspended above it.

In comparing the influence of different metals, each disc had the same diameter and the same velocity; and the following were the results which were obtained by this and another method of observation:—

	Ratio of the Force to that of Copper.	Ratio by another Method.
Copper	1·00	1·00
Zinc	0·90	1·11
Tin	0·47	0·51
Lead	0·25	0·25
Antimony	0·11	0·01
Mercury	0·00	0·00
Bismuth	0·01	0·00
Wood	0·00	0·00

The second method of observation by which the results in the last column were obtained was more expeditious than the first. Portions of different bodies of the same form and dimensions were suspended above a revolving magnet, and the time of successive oscillations and the points of equilibrium were observed.

Our authors next sought to determine the effect produced by a solution of continuity in the metallic disc upon which the revolving magnet acted. For this purpose a disc of lead, 12 inches in diameter and $\frac{1}{10}$th of an inch thick was suspended at a given distance from a horse-shoe magnet revolving with the ordinary rapidity, first in its entire state, and afterwards in the state shown in figs. 28, 29, 30, 31, 32; the black lines in the direction of the radii being the planes where the lead was cut through. The accelerating forces

Development of Magnetism in all Bodies by Rotation.

represented by $\frac{s}{t^2}$, where s is the number of the revolutions, and t the time employed, are as follow:—

Uncut Disc.	Disc as in fig. 28.	Disc fig. 29.	Disc fig. 30.	Disc fig. 31.	Disc fig. 32.
1258	1047	913	564	432	324

Effects similar, but differing in degree, were obtained with other metals. With soft tinned iron the cutting produced a very slight diminution of effect, whilst in copper the same operation reduced the accelerating force in the ratio of five to one.

Development of Magnetism in all Bodies by Rotation.

Messrs Babbage and Herschel next tried the effect of filling up the cuts with other metals. A light copper disc, suspended at a given distance above a revolving magnet, performed six revolutions in 54·8. When it was cut, as in fig. 32, its magnetic action was so weakened that it took 121·3 to perform six revolutions. When the eight open radial spaces were filled up with tin, its magnetic action was restored to such a degree that it made six revolutions in 57·3. This fact is very interesting, as tin has less than half the energy of copper. The following results were obtained from other experiments, the numbers representing the accelerating forces or the magnetic energies developed in the plates:—

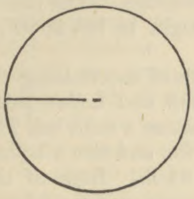

Fig. 28.

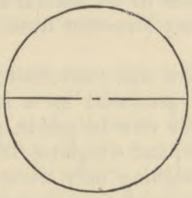

Fig. 29.

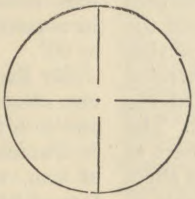

Fig. 30.

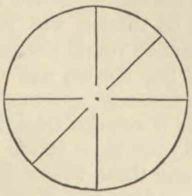

Fig. 31.

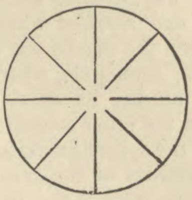

Fig. 32.

Brass not cut	1·00
Brass cut	0·24
Brass soldered with bismuth	0·53
Brass soldered with tin	0·88
Copper not cut	1·00
Copper cut	0·20
Copper soldered with tin	0·91

Law of the force.

In determining the law of the force in relation to the distance, Messrs Babbage and Herschel found it to vary between the ratio of the square and the cube of the distance. Mr Christie found, that when the revolving disc was thick and the needle delicate, the force which produced the deviation of the needle increased directly as the velocity of rotation, and inversely as the fourth power of the distance. MM. Prevost and Colladon found that the angles of deviation, and not their sines, increased in the direct ratio of the velocity, at least within certain limits; and that the sines of the angles of deviation were in the inverse ratio of the two and a half power of the distance.[1]

Experiments of M. Haldat;

M. Haldat made some interesting experiments on this subject. He found that every needle, however weak was its magnetism, obeyed the action of the revolving disc; but that this action disappeared entirely when its polarity disappeared. He found it impossible to magnetize needles by the action of the revolving disc, however rapid; and ascribing this effect to the want of coercive power, he employed discs of iron and steel, both soft and hardened.

A disc of soft iron acted with more energy than one of copper, and with the same velocity it dragged the needle twice the distance that a disc of brass did. Iron strongly hammered acted like soft iron, and was unable to give polarity to a steel needle. But a disc of untempered steel $\frac{1}{25}$th of an inch thick did not produce any appreciable effect on the magnetic needle, which, after a few irregular oscillations, maintained its ordinary position of equilibrium. Hence M. Haldat concluded that the force which acted upon it was in the inverse ratio of the coercive force. He also found that discs in a state of incandescence exercised the same action as those at the ordinary temperature.

of Mr Barlow.

We have already seen, in our historical detail, that about six months previous to the announcement of M. Arago's discoveries, M. Barlow had announced to the Royal Society of London the result of a series of experiments on the magnetic effects produced by iron in rotation. Having found that an iron ball performing 640 revolutions in a minute caused a magnetic needle to deviate several degrees, and to take a fixed position during the continuance of the motion; that the needle deviated in an opposite direction when the motion of the ball was reversed; that there were certain positions in which a bomb 12 inches in diameter, moved by a steam-engine, occasioned no deviation in the needle; that in some positions the deviation was in one direction, and in other positions in another; and that the deviation varied between 0° and 80°; he constructed a regular apparatus for determining the laws of these phenomena, and in which the iron which formed part of it should not influence the results. This apparatus is shown in fig. 33, where S is an iron sphere, made to revolve on a horizontal axis AB, by means of two wheels, like an electrical machine, their diameters being as six to one, so as to perform 720 revolutions in a minute. A table LM was placed near the sphere, for holding the needle, so that the needle could be placed in any position, either above or below the sphere. The table LM being brought to the height of the axis AB, the needle was placed successively in different positions round the sphere. The influence of the earth's magnetism on the needle being destroyed or neutralized by the action of a magnet properly placed for this purpose, and shown at NS standing vertically, Mr Barlow found, that whatever was the azimuth of the needle, its *north pole* approached the sphere S when the upper part of the sphere was moving *towards* the needle, and that its *south pole* ap-

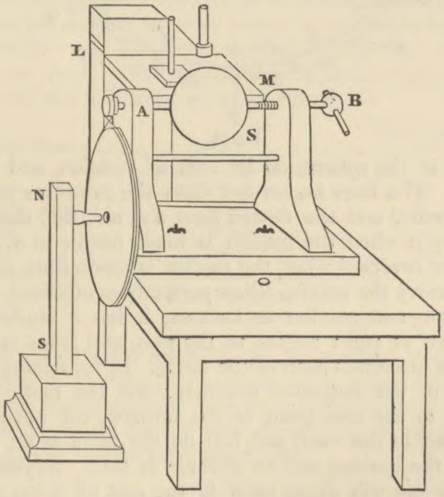

Fig. 33.

---

Development of Magnetism in all Bodies by Rotation.

proached the sphere when the upper part moved *from* the needle.

Having placed the axis of rotation sometimes in the magnetic meridian, sometimes in the direction of east and west, and sometimes in intermediate positions, he found, that whatever was the direction of the axis of rotation, the needle being always a tangent to the sphere, the *north* end of the needle was *attracted* when the sphere moved *towards* the needle, and *repelled* when its motion was *from* the needle. When the needle was carried round the revolving sphere in the semicircle, where the motion was directed towards the needle, its *north* extremity *approached* the sphere, and in the other semicircle it *receded* from it. The points where the sphere exercised upon it no action were at the two extremities of the axis, and those where the effect was a maximum were at the two extremities of an axis at right angles to this. In this case the direction of the needle was towards the centre of the ball.

The different positions of the needle are shown in fig. 34, where *s* is the sphere, *ab* its axis of rotation, and *cd* its equator. The lines *ns*, *ns*, &c., show the primitive position of the needle, and the dotted lines *n's'*, *n's'*, &c., those assumed by it when the motion is made from *c* to *d*. The effects are reversed when the motion is made from *d* to *c*.

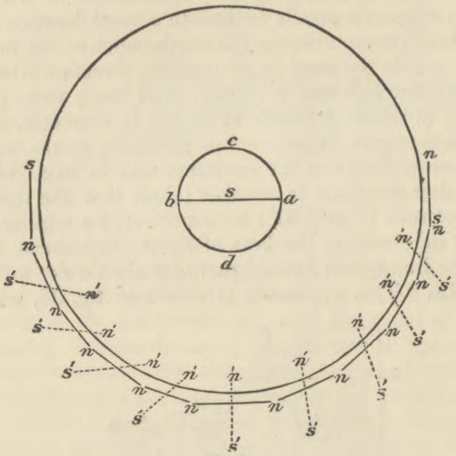

Fig. 34.

If we carry the needle, when perfectly neutralized, round the sphere, and parallel to its axis, it has a tendency to place itself at right angles to the axis, and takes opposite directions at certain parts of the circle. If, for example, the axis be in the magnetic meridian, and the motion from the west to the east point of the horizon, the needle will direct itself to the west, and will do the same at all points between the horizon and an altitude of 60°. Beyond this the north end will direct itself to the east till it has passed the zenith 30° to the west; and then from this point to the west horizon, the north extremity will direct itself to the west; and similar changes will take place under the sphere. The same effects are produced whatever be the direction of the axis and that of motion.

When a magnetic needle *not neutralized* is placed in different positions round the sphere whose axis is in the magnetic direction, the effects produced are as shown in fig. 35, where AB is the axis of rotation, the black lines representing the natural deviations of the needle, and the dotted ones those which it assumes when the sphere is in motion. Beginning at the point A, if the motion be from left to right, that is, from west to east, the needle moves from *n* to *n'* in the same direction till it arrives at 30°. It then remains in its natural direction. The needle moves in a contrary direction from right to left at 60°, 75°, and at 90°.

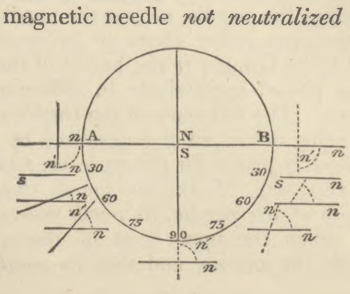

Fig. 35.

Effects of a hollow ball.

Mr Barlow was next desirous of ascertaining the different effects produced by a solid and hollow ball of iron, and with this view he put in motion a solid ball 7·87 inches in diameter, and weighing 68 lb., and also a hollow sphere of iron, weighing only about 34 lb. Both of them performed 640 revolutions in a minute, and the following were the average results:—

			Weight.
Mean deviation of the solid ball	28°	24′	68 lb.
Mean deviation of the hollow ball	15	5	34

When the two balls were at rest, the difference of their action was nothing.

Experiments of Mr Christie.

Mr Barlow's paper on rotation was communicated to the Royal Society on the 14th April 1825, and on the 20th Mr Christie communicated one *On the Magnetism of Iron arising from its Rotation.* Mr Christie's experiments were made with circular plates of iron put in motion by an ingenious piece of machinery, by which he could make the plate revolve in every possible plane in reference to the magnetic meridian. From a great body of well-devised experiments, he obtained the following general law of the deviation due to rotation, so that the direction of the rotation being given, he could tell the direction of the deviation. This law we must give in his own words:—

"I refer the deviations of the horizontal needle to the deviations of magnetic particles in the direction of the dip, or to those of a dipping needle passing through its centre; so that, in whatever direction this imaginary dipping needle would deviate by the action of the iron, the horizontal needle would deviate in such manner as to be in the same vertical plane with it; thus, when the north end of the horizontal needle deviates towards the west, and consequently the south end towards the east, I consider that it has obeyed the deviation of the axis of the imaginary dipping needle, whose northern extremity has deviated towards the west, and its southern towards the east; so that the western side of the equator of this dipping needle has deviated towards the south pole of the sphere, and its eastern side towards the north pole. It would follow from this, that if the north and south sides of the equator of the dipping needle (referring to these points in the horizon) deviated towards the poles, no corresponding deviations would be observed in the horizontal needle; the effect, in this case, taking place in the meridian, would only be observable in the angle which the dipping needle made with the horizon. As it is not my intention at present to advance any hypothesis on the subject, I wish this to be considered only as a method of connecting all the phenomena under one general view. Assuming it, then, for this purpose, it will be found that the *deviations of the horizontal needle due to rotation* are always such as would be produced *by the sides of the equator of this imaginary dipping needle deviating in directions contrary to the directions in which the edges of the plate move,* that edge of the plate nearest to either edge of the equator producing the greatest effect on it."

From another set of experiments, Mr Christie also found that the effect produced on the iron by its rotation is permanent so long as the plate remains stationary; that it is independent of friction; that it is so far independent of velocity, *that the iron can scarcely be moved so slowly that*

Influence of Heat on Magnetism.

the whole effect shall not be produced; and that the whole effect is produced by making it perform one-fourth of a revolution. After Mr Christie had discovered these peculiar effects, he exhibited some of the phenomena to Mr Barlow, who conceived that the effect would be increased by rapid rotation, and who was thus led to make the experiments of which we have already given an account; but the phenomena differ essentially from those observed by Mr Christie; the former being temporary and dependent on velocity, while the latter are permanent, and independent of the rapidity of rotation.

In comparing the magnetic forces produced by rapid and slow rotation, Mr Christie found that the forces exerted on the needle during the rapid rotation of the plate are always in the same direction as the forces which are derived from the slowest rotation, and which continue to act after the rotation has ceased; but that the former forces are greater than the latter. From a mean of all the observations, the forces seem to be in the ratio of seventeen to thirteen, or very nearly of three to two. Hence Mr Christie conceives that the polarizing of the iron in the same direction will account for the phenomena in both cases; but that the intensity of the polarity during the rapid rotation is greater than of that which appears to be permanent after the rotation, whether slow or rapid, has ceased; and that the phenomena observed during rapid rotation are such as should be expected from what have been described as arising from rotation, without regard to its velocity.

Experiments of Mr Snow Harris.

We have already seen that Messrs Babbage and Herschel interposed plates of various metals between the revolving magnet and the copper disc, and found no perceptible effect to be produced. Mr S. Harris,[1] however, has more recently shown that several substances not supposed to contain iron have the power of intercepting the influence of a revolving magnet. A circular magnetic disc being delicately balanced on a fine central point by means of a rim of lead, was put into a state of rotation on a small agate cup, at the rate of 600 revolutions in a minute; and a light ring of tinned iron, also finely balanced on a central pivot, was placed immediately over it, at about 4 inches distance, by means of a thin plate of glass, on which its pivot rested. When the ring of tinned iron began to move slowly on its pivot by the influence of the magnet revolving below, a large mass of *copper*, about *three* inches thick, and consisting of plates a foot square, was carefully interposed between the magnet and the iron ring. The interposition of the copper soon sensibly diminished the motion of the iron disc, and at length *arrested it altogether.* On again withdrawing the copper, the motion of the disc was restored; and the same effects were repeatedly obtained. In this experiment both the magnet and the disc were inclosed by glass shades, and supported on a firm base.

The same effects were produced by a mass of silver and zinc; but when their thickness was considerably diminished by removing the central plates, the motion of the disc was not impeded. A very great thickness of *lead* was necessary to stop the disc, in consequence, as Mr Harris supposes, of its magnetic energy being so much less than that of copper.

CHAP. V.—ON THE INFLUENCE OF HEAT ON MAGNETISM.

Influence of heat on magnetism.

This interesting department of magnetism divides itself into three parts: 1*st*, On the effect of heat on the development of free magnetism; 2*dly*, On the anomalous attraction observed during the bright red and red heats; and, 3*dly*, On the effect of heat on the distribution of magnetism in magnets.

SECT. I.—*On the Effect of Heat on the Development of Magnetism in Cast and Malleable Iron.*

In cast and malleable iron.

In the course of his experiments on the relative magnetic powers of different kinds of iron and steel, already given in the history of magnetism, Mr Barlow was led to the conclusion that the harder the metal was, the less it exhibited of a magnetic quality: a result which was highly favourable to the hypothesis, that the cohesive power of hardened steel not only prevented the entire development of its magnetism, but also the re-combination of the two kinds of magnetism when they were displaced by the action of a powerful magnet. With the view of establishing this hypothesis, Mr Barlow found it necessary to ascertain whether these different kinds of iron and steel would exhibit the same magnetic powers when reduced to the same degree of softness, which could only be done by heating them in a furnace, and trying their magnetic qualities in that state.

Having procured a bar of soft iron 25 inches long and 1¼ square, and a cast-iron one of nearly the same dimensions, he inclined the bars in the direction of the dip; and having placed a magnetic needle nearly on a level with the upper extremity, and at the distance of 6 inches from it, he observed the deviations produced by the bars in different states of heat. Thus,—

		Mean deviation.	
Cast iron	Cold	21°	30′
Ditto	White heat	0	0
Ditto	Blood-red heat	62	0
Malleable iron	Cold	40	0
Ditto	White heat	0	0
Ditto	Blood-red heat	55	0

These experiments were often repeated with the same results. It deserves to be remarked as a singular result, that cast iron is decidedly inferior in its action when cold, and when hot possesses a superior power to malleable iron.

Mr Barlow now compared malleable iron with soft and hard shear steel. The bars were 24 inches long and 1¼ square, and the following were the results:—

		Mean deviation.	
Malleable iron	Cold	15°	10′
Ditto	White heat	0	0
Ditto	Blood-red	41	11
Soft shear steel	Cold	11	0
Ditto	White heat	0	0
Ditto	Blood-red	48	0
Hard shear steel	Cold	8	0
Ditto	White heat	0	0
Ditto	Blood-red	47	30

These experiments establish the curious fact of the total destruction of the magnetic virtue by a *white heat;* and also the no less important one, that every kind of iron or steel has a greater capacity for developing its magnetism when softened by fire than when cold.

SECT. II.—*On the Anomalous Attraction observed in Cast and Malleable Iron during the Bright Red and Red Heats.*

Anomalous attraction of iron at a red heat.

In pursuing the preceding researches, Mr Barlow was led to observe a remarkable anomaly in the action of the iron at the red heat. When iron brought to a white heat has wholly lost its power, it again acquires, as it passes into the bright red and red, a magnetic power; but what is truly strange, its power is *attractive* for the south end of the needle; that is, if the *north* pole of the needle was attracted when the iron was cold, the *south* end will be attracted when the iron is at a bright red heat.

In order to investigate this subject thoroughly, Mr Barlow made a very extensive series of experiments with four

---

[1] *Phil. Trans.*, 1831, p. 497.

Influence of Heat on Magnetism.

different bars, each 25 inches long and 1¼ square, two of them being of cast, and two of malleable iron. He used also other two bars, one of cast and one of malleable iron, of the same dimensions, which were kept as standards to determine the quantity of cold attraction. The time employed in each experiment was a quarter of an hour: the white heat generally continued about *three* minutes when the negative attraction commenced. This attraction lasted about *two* minutes more, when the usual attraction began. This sometimes reached its maximum with great rapidity, but at other times it increased very gradually. The following table contains the results of Mr Barlow's experiments. The letters CB denote the cast-iron bar, and MB the malleable-iron bar; and the sign + indicates when the ordinary attraction of the iron takes place; and − the anomalous or negative attraction.

Influence of Heat on Magnetism.

Table of the Results of Mr Barlow's Experiments on the Effect of Iron on the Compass Needle at different Degrees of Heat.

N.B.—We have omitted the column for white heat, as no effect is ever produced at that temperature.

No.	Description of Bar.	Height and Depth of Centre of Bar from Needle.	Distance of Bar from Needle.	Position of Needle.	Effect when Cold.	Effect of Red Heat.	Effect at Blood-red Heat.	Remarks.

37	M. B. No. 1	0·0	4·7	W.	+ 3 30	− 50 0	+ 8 0	Motion regular, but quick.
38	M. B. No. 2	0·0	4·7	N.	0 0	0 0	0 0	No motion in the needle.

Anomalous action of red-hot iron.

One of the most remarkable results of these experiments is, that the anomalous action of the bar between a bright-red and blood-red heat *increases* as we raise the bar above the needle, and becomes a *maximum* at the centre of the bar; whereas at low temperatures the action of a bar of iron under the very same circumstances goes on diminishing as the bar is raised, and becomes a minimum at the centre. When the needle is placed at the height of the centre of the bar, when heated to produce the anomalous effect, the smallest displacement is sufficient to change the sign and the quantity of the deviation.

Mr Barlow made some experiments with a twenty-four pound ball of iron, but the heat was too intense to allow any very accurate observations to be made. The results however, were as follow:—

Cold attraction	+ 13° 30′	deviation.
Red heat	− 3 30	...
White heat	0 0	...
Blood-red heat	+ 19 20	...

No effect whatever was produced on the needle by heated bars of copper.

In order to explain the singularly anomalous action above described, Mr Barlow supposed, that during the cooling of the bars, the extremities where this cooling is most rapid become magnetic before the rest of the metal, and that there results from this a complex action. He allowed, how-

Influence of Heat on Magnetism.

ever, that this supposition does not sufficiently explain all the observed phenomena. The explanation given by Professor Kupffer is more satisfactory. In weakly magnetized bars the points of indifference are very near the extremities; but in Mr Barlow's experiment the magnetism communicated to soft iron by the earth being nothing at a bright-red, and reaching its maximum at a blood-red heat, there is probably formed a point of indifference at each extremity of the bar. If this is the case, the raising of the bar places the needle in front of points which are beyond the point of indifference, and which possess a magnetism opposite to that of the extremity itself. At the first epoch of cooling, this opposite magnetism should even increase to a certain point, and the more as we approach the middle of the bar; but in proportion as the magnetism of the bar increases, the point of indifference will approach its middle, and the phenomena of ordinary attraction reappear.

M. Kupffer's explanation.

SECT. III.—*On the Effects of Heat on the Distribution of Magnetism in Magnets.*

Effect of heat on the distribution of magnetism.

M. Coulomb was the first philosopher who investigated the important subject of the influence of heat on the distribution of magnetism in needles and magnets.[1] He took a bar of steel 162 millimetres long, 14 wide, and weighing 82 grammes. This bar was brought to a cherry-red heat, about 900°, and cooled slowly in the air, so as to have no temper. It was then magnetized to saturation at the temperature of about 12° Reaumur. In this state the time of making *ten* oscillations was observed. Its temperature was again raised successively so many degrees, and after being cooled, the time of performing ten oscillations was again measured. The following were the results:—

Temperature in degrees of Reaumur.	Time of performing Ten Oscillations.
12°	93^s
40	97·5
80	104
211	147
340	215
510	290
680	very great.

Hence it is obvious that the magnetic intensity of the bar diminishes rapidly as its temperature is raised.

From another set of experiments, Coulomb concludes that the tempering of a bar previous to its being magnetized has no influence until the heat at which it is tempered becomes about 750°. When the tempering is at 900°, the bar will take double the magnetic force that it did at 12°; the ratio of the time of ten oscillations being 63^s and 93^s, the squares of which, to which the magnetic forces are proportional, are nearly as one to two.

After the magnet had received the hardest temper at 950°, it was magnetized to saturation. When it was brought back, by annealing, to lower temperatures, and again magnetized, the effects were as follow:—

Temperature.	Time of Ten Oscillations of a Bar tempered at 95°.
12°	63^s
80	66
214, blue colour	80
410, colour of water	170

Hence we see that the progressive rise of temperature alters the magnetism of the bar much more when it had been first tempered towards 900° and cooled slowly, than when it had been first put into the annealed state.

When in the annealed state the bar is exposed only to temperatures below 500°, it receives its original force by being again magnetized; but in the state of temper it is not so. Each rise of temperature diminishes perceptibly the magnetic force which the bar can receive from being again magnetized. This is shown in the following table:—

Influence of Heat on Magnetism.

Annealing Temperature.	Time of performing Ten Oscillations when again magnetized.
12°	63^s
214	64·5
410, colour of water	70
900, cherry-red	93

The bar, therefore, attained its maximum energy when tempered at 900°. It then performed ten oscillations in 63^s Setting out from this term, the directive force diminished in proportion as the annealing temperature increased. At 900° the bar, magnetized anew to saturation, employed 93^s to make ten oscillations, as in the first experiments, which ought to have been the case, as it was brought back to the same state of perfect annealing from which it was at first taken.

The bars used by Coulomb were about thirty times as long as they were thick, and with such bars similar results were always obtained. But this was not the case with larger bars. Having taken a steel wire 326 millimetres long, and 4 in diameter, he tempered it at 820°, magnetized it to saturation, and determined its directive force. He repeated the same operation after having annealed it at different temperatures, and the following were the results:—

Annealing Temperature.	Time of Ten Oscillations.
12°, temperature of atmosphere	89^s
320, colour of water	75
450, deep red	68
530, less deep red	70
900, bright cherry-red	76

Here the hard temper gives the weakest directive force, as we have already seen in the preceding experiments. The maximum effect takes place when the wire is annealed at about 450°, and this result is a general one for all wires and plates whose length is very great relative to their width.

This result seems to be connected with a particular mode of distribution of free magnetism. In bars whose length does not exceed thirty times their diameter there is never more than one magnetic centre, which is in the middle of the bar. But when the ratio of the length to the breadth is greater than this, magnetizing it produces always three centres, one in the middle of the bar, and the other two at equal distances from its extremities. This effect is shown in fig. 36, and in fig. 37. The effect of placing such a magnet in iron filings is shown in fig. 37; and in fig. 36 the curve of the intensities is seen to cross the axis between the centre C and the poles A, B, the two new centres being at C′ and C″.

Fig. 36.

Fig. 37.

M. Coulomb found that the distance C′A, C″B of the two new centres from the extremities of the magnet varies with the temper, and the annealing heat is shown by the following results obtained with a wire-magnet 326 millimetres long:—

---

[1] Biot, *Traité de Physique*, tom. iii., p. 106.

Influence of Heat on Magnetism.

	Time of Ten Oscillations.	Distances of the Centres C′, C° from the Centre C, the Middle of the Magnet.	
		C′	C°
Hard temper	89	98	98
Annealed at the colour of water	75	63	63
Ditto at dark-red heat	68	43	43
Ditto at cherry-red	76	0	0

In proportion as the annealing heat increases, the two centres C′, C″ approach each other, and are reunited with the centre C at a cherry-red heat. This last result is very important in the construction of compass-needles. Coulomb regards the *dark-red* as the best annealing heat for needles or bars whose length exceeds thirty times their thickness, and the state of hard temper for those where the ratio between the length and the thickness is less.

It is extremely probable, as M. Biot supposes, that when magnets are larger in proportion to their thickness than those used in the preceding experiments, a greater number of centres will be produced, were it from no other cause than the reaction of the plate upon itself.

M. Kupffer's experiments.

In examining the influence of temperature on magnets, Professor Kupffer began by examining the effect of heat in altering the distribution of magnetism. For this purpose he took a parallelopiped of tempered steel, 503 millimetres long, 15½ wide, and 5 thick, and having magnetized it to saturation, he heated it, and allowing it to cool slowly, he submitted it to examination. The magnet was placed vertically, as at *a′b′*, and a needle suspended by a silk fibre was made to oscillate before any point *ab*, in order to determine the intensity of magnetism at that point. In this way he obtained the following results:—

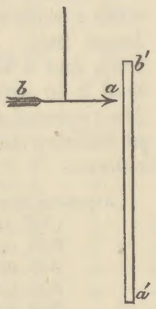

Fig. 38.

Distance *ab′* in Millimetres.	Magnet not heated.	Same Magnet heated to 80°, and examined after cooling.
	Magnetic Force.	Magnetic Force.
156	0·5569	0·4376
136·5	0·7374	0·5765
116·5	0·9455	0·7280
96·5	1·1862	0·8897
76·5	1·4311	1·0559
56·5	1·6518	1·1929

Hence it appears that the bar heated to 80° had not only lost much of its magnetic virtue, but that this loss was not uniform along the whole length of the bar, being greater towards the extremities *a′*, *b′* than towards the middle. This may be easily seen by dividing the forces in columns 2 and 3 by one another, when it will appear that the quotients are greater for points nearest *a′* and *b′*.

M. Kupffer next studied the changes which take place in the forces of a magnetic needle when its temperature is increasing, the heat being kept constant during the time of each experiment. He used a cylindrical needle of fused steel, 0·57 millimetre long, and 2·395 grammes in weight. The temperature increased from 8½° to 18°, and the deviation of 300 oscillations varied from 777½ to 781, which shows, as Coulomb had previously observed, that the magnetic force diminished as the temperature increased. By another series of experiments, M. Kupffer has shown that the diurnal variations of the needle did not at all affect these results.

In order to determine the law of the decrease of the magnetic forces at temperatures above 30°, he made a needle oscillate above a newly magnetized bar 0·5 millimetre long, the opposite poles looking to each other, and he raised the temperature of the bar from 13° to 80° by means of hot water. At 13°, the needle, when by itself, performed 300 oscillations in 762^s, and in presence of the magnet it lost only 429^s. When brought to the temperatures in the table, and then cooled, the oscillations of the needle were observed.

Influence of Heat on Magnetism.

Temperature of the Magnet.	Duration of 300 Oscillations.
13° Reaumur	429 seconds.
80 ...	476
21 ...	464½
13 ...	463
11 ...	462½

Hence it appears that the magnetic force diminishes with heat, and that a magnet at the temperature of 13°, when heated to 80°, and then cooled to 13, does not resume its first magnetic state, which is diminished. The cause of this is, that in cooling slowly the bar loses a part of its temper, and consequently a part of its free magnetism.

From these observations M. Kupffer deduces the following formulæ, which represent with great accuracy the influence of temperature, viz.:—

$$x = \frac{n}{\sqrt{c + \mathrm{F}}}$$

$$x = \frac{n}{\sqrt{\left(c + \mathrm{F} - \frac{(1-q)^{\mathrm{F}}}{67}\right)(t-13)}},$$

where c is the force exerted by the earth on the oscillating needle.

x, the number of seconds in which n oscillations are made.

F, the force exerted by the bar at the same temperature.

x', the number of seconds which the same needle employs at the temperature t.

p, the intensity of the magnetic force of the bar at 13°; and

q, the intensity of the same force at 80°.

M. Kupffer proceeded to examine the effects which the heating of only one pole of a magnet produced upon the distribution of its magnetism. With this view he placed a magnet parallel to a needle suspended horizontally, the dissimilar poles being placed opposite to each other. The needle will not remain in the magnetic meridian unless its neutral point and that of the bar are in the same line perpendicular to the needle. This position may be found by a few trials. When, by shifting the magnet, its neutral point approaches one of the poles of the needle, and always in the same direction, this pole will be repelled, because the opposite pole of the needle is more strongly attracted by the corresponding pole of the magnet, which is brought near it, while the other is removed from it.

Let us now heat the north pole of the magnet; the south pole of the needle opposite to it will be attracted. Hence it is clear that the point of indifference, or neutral point, has receded from the heated pole, or from the pole whose magnetic intensity is diminished, which agrees with the law of Coulomb. The following results were obtained with a magnet 0·5 millimetre long, the needle being placed in the magnetic meridian:—

Temperature of the extremity of the Bar.	Duration of 100 Oscillations.
0° Reaumur.	275·5 seconds.
13 ...	276
40 ...	278
56 ...	279·5
15 ...	277·5
11 ...	277

When the magnet had cooled slowly, the needle returned gradually to its first position; but it never recovered it entirely. By the earth's action only, the needle performed 50 oscillations in 207^s.

When a bar of soft iron was substituted for the magnet,

Action of Simple Iron Bodies on the Magnetic Needle.

and placed in the magnetic meridian, it was magnetized by the action of the earth. When one of its extremities was heated, the pole of the needle next it was *attracted* instead of *repelled*, the neutral point having *approached* to the heated extremity, in place of *receding* from it as formerly. Hence the magnetic force of the iron was *increased* by heat.

Mr Christie's experiments.

In examining the diurnal deviations of the needle when under the influence of magnets, Mr Christie conceived that the deviations might be partly the effect of changes in the temperature of the magnets; and he therefore undertook a series of experiments to determine the precise effects of changes of temperature on magnets. By a peculiar apparatus, and a method of observation which our limits will not allow us to introduce, he obtained the following results:—

Mean Temperature of the Magnets. Fahr.	Difference of Heats in successive Observations.	Magnetic Intensity.	Variation of Intensity for 1° of Fahr.
62°·05	− 3°·00	212·5620	0°·1268
59 ·05	+18 ·60	212·9423	0 ·1247
77 ·65	− 3 ·65	210·6228	0 ·1004
74 ·00	− 3 ·35	210·9892	0 ·1279
70 ·65	− 3 ·50	211·4178	0 ·1193
67 ·15	− 3 ·35	211·8353	0 ·1138
63 ·80	− 1 ·75	212·2167	
62 ·05		212·4640	0 ·1413

By discussing these results, Mr Christie concludes that 0·1226 is the mean variation of the intensity of the magnets, from a change in their temperature of 1° between the temperatures of 59°·05 and 77°·65. Taking the case where the intensity at 60° was 218, the change for 1° was 0·123; and supposing the intensity to be 1, each degree will produce a diminution of 0·000564.

From a number of experiments made with a balance of torsion, the needle being suspended by a brass wire $\frac{1}{460}$th of an inch in diameter, Mr Christie ascertained the following facts:—

1. Beginning with −3° of Fahrenheit, up to 127°, the intensity of magnets decreased as their temperature increased.

2. With a certain increment of temperature the decrement of intensity is not constant at all temperatures, but increases as the temperature increases.

3. From a temperature of about 80°, the intensity decreases very rapidly as the temperature increases; so that if, up to this temperature, the differences of the decrements are nearly constant, the differences in the decrements also increase.

4. Beyond the temperature of 100° a portion of the power of the magnet is permanently destroyed.

5. On a change of temperature, the most considerable portion of the effect on the intensity of the magnet is produced instantaneously, showing that the magnetic power resides on or very near the surface.

6. The effects produced on soft iron by changes of temperature are directly the reverse of those produced on a magnet; an increase of temperature causing an increase in the magnetic power of the iron. This was observed between the temperatures 50° and 100° Fahr. Mr Christie regards this fact as a strong argument against the hypothesis, that the action of iron upon the needle arises from the polarity which it receives from the earth.[1]

CHAP. VI.—ON THE ACTION OF SIMPLE IRON BODIES ON THE MAGNETIC NEEDLE.

Action of simple iron bodies on the needle.

Mr Barlow undertook the interesting experiments which we are about to describe, with the view of discovering some method of correcting the local attraction of a ship's guns and other iron on the compass-needle.

Action of Simple Iron Bodies on the Magnetic Needle.

His attention was first directed to the action of solid spheres and spherical shells of iron; but he afterwards applied the principles to which he was led to the action of bars and plates of simple iron, and to irregular masses. We shall therefore lay before our readers, in three separate sections, the results of his experiments and theoretical investigations respecting these two forms of unmagnetized iron.

SECT. I.—*On the Action of Spheres and Spherical Shells of Iron on the Magnetic Needle.*

Action of spheres on the needle.

The earliest experiments of Mr Barlow, by which he was led to some of the properties of iron spheres, were made in an imperfect manner; but the phenomena were such as to induce him to construct an apparatus capable of affording him the most accurate measures of the deviation of the needle.

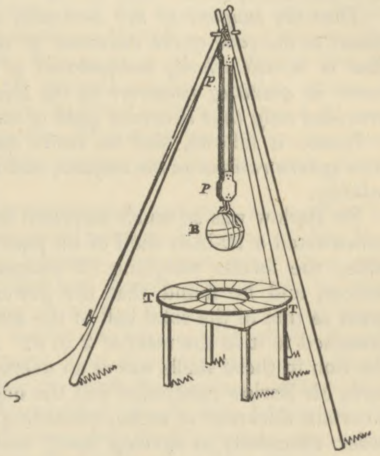

Fig. 39.

The apparatus which he finally employed is shown in fig. 39. It consists of a large and steady round table TT, having its surface horizontal. The points of the compass are laid down on its upper face. In its centre is a hole 18¼ in. wide, for receiving an 18-inch or smaller iron shell or ball B, which is suspended above it by pulleys *p*, *p*, which allow the observer to raise or lower it at pleasure. When a diameter of this table is brought into the magnetic meridian, Mr Barlow found, that in whatever part of the table a compass-needle was placed, except in the meridian, the *south* end of the needle was drawn to the ball when the latter was wholly above the table, as in the figure. The attraction increases as the ball descends, till at a certain point it is a maximum, and then decreases again towards zero as the ball descends farther. Hence it is clear, that there is all round the ball a position where the attraction is zero; and it was easily observed that these points lay in a plane inclined to the horizon. In this way Mr Barlow established his fundamental principle, that—

In every ball or shell of plain unmagnetized iron there exists a plane of no attraction, or a plane in which the iron produces no disturbance on the needle, and which plane inclines from north to south (magnetic), forming with the horizon an angle equal to the complement of the dip.

This line on the surface of the ball may be called the magnetic equator; and, taking the meridian which passes through the east and west points as the first, Mr Barlow is able to designate every part of his iron sphere by the magnetic longitude and latitude of that point.

Mr Barlow therefore proceeded to determine whether the quantity and deviation at any point could be expressed by any function of the latitude and longitude of that point, when the mass of the ball and the distance of the needle from it were constant. From these experiments, which it is unnecessary to detail, he found—

---

[1] See *Philosophical Transactions*, 1825, p. 1-65.

Action of Simple Iron Bodies on the Magnetic Needle.

Professor Barlow on the action of iron spheres.

That the tangent of the deviation of the needle is proportional to the rectangle of the sine and cosine of the latitude, or to the sine of the double latitude.

By observing the deviations throughout a great circle in which the longitude was constant, and also in a circle in which the latitude and longitude were variable, he found the following law:—

That the tangent of the deviation of the needle is nearly proportional to the sine of the double latitude multiplied by the cosine of the longitude.

By comparing the constant numbers obtained on the preceding principles at different distances *from the centre of the sphere,* Mr Barlow found,—

That the tangent of the deviation is inversely proportional to the cube of the distance.

The remaining object of Mr Barlow's inquiry was a very interesting one, namely, to determine the law of the deviation as dependent on the mass of the iron ball by the action of which it was produced. The result was equally new and unexpected. He found,—

That the tangent of the deviation was directly proportional to the cube of the diameter of the ball or shell; but that it is still wholly independent of the mass, being the same in quantity whatever be the thickness of the metal, provided only that it exceed $\frac{1}{20}$th of an inch.

Hence it follows, *that the entire magnetic power of an iron sphere resides on the surface, and is independent of the solidity.*

Mr Barlow was so much surprised at this result, that he constructed a 10-inch shell of tin plate and another of iron plate, the former weighing 43 ounces and the latter 45 ounces, and he found that the power of neither was so great as that of the solid ball of the same diameter, but approached to it in the ratio of 2 to 3. As the thickness of the iron in these shells was at an average about $\frac{1}{30}$th of an inch, Mr Barlow concluded that the magnetic fluid requires a certain thickness of metal, exceeding $\frac{1}{30}$th of an inch, in order effectually to develop itself, and act with its maximum energy.

This important result was some time afterwards verified by Captain Kater, with three cylinders, one of soft iron, and $\frac{1}{10}$th of an inch thick; another of what is called chest-plate, 0·185 of an inch thick; and the third solid. The deviations produced by these three cylinders, when reduced to the same extent of surface, were 141, 184, and 187, thus proving that the cylinder whose thickness was only 0·185, or between $\frac{1}{5}$th and $\frac{1}{6}$th of an inch thick, had the same magnetic power as a solid cylinder of iron. The distribution of magnetism on the surface of magnetic bodies presents us with another interesting analogy between the magnetic and electric fluids; and it deserves our particular notice, that in the results obtained by Mr Barlow, the action of the sphere is related to the centre of its mass, and not to the poles of its magnetic equator.

Mr Barlow next proceeds to the investigation of analytical formulæ, which shall exhibit the action of iron spheres upon a magnetic needle. In this inquiry he sets out with the established experimental fact already mentioned, *that the entire magnetic power of an iron sphere resides on the surface, and is independent of the solidity;* and he proceeds on the following hypothesis:—

1. Magnetic phenomena are due to the existence of two fluids in a greater or less degree of combination, and such that the particles of the same fluid repel, and those of an opposite nature attract, each other.

2. These fluids in iron bodies exist naturally in a state of combination and equilibrium till that state is disturbed by some exciting cause.

3. But if a body already magnetic, *i.e.*, one in which the fluids are held in a state of separation, be brought within the vicinity of a mass of iron, such as is supposed above, the concentrated action of each fluid in the magnetized body will act upon the latent fluids in the quiescent body, by repelling those of the same, and attracting those of the contrary kind, and thus impress upon the latter a temporary state of magnetic action, which will remain only while the two bodies maintain their respective situations.

Action of Simple Iron Bodies on the Magnetic Needle.

Professor Barlow on the action of iron spheres.

4. The quantity of action impressed upon the iron body will depend, 1*st*, upon the intensity of the exciting magnet; 2*dly*, upon the capacity of the quiescent body for magnetism, or the quantity of those fluids contained in it; and, 3*dly*, upon the cohesive power of the iron; which latter quality determines the depth to which the exciting magnet is able to disengage the two fluids.

The above embraces every case, namely, of any magnet, natural or artificial, developing the magnetism in any given iron body; but the displacement occasioned by the magnetic action of the earth, or spheres of iron, is more limited in its results, and more susceptible of correct mathematical investigation.

5. In this case, for instance, we may suppose the action to take place on every particle of the mass in lines parallel to each other, and corresponding in direction with the dipping needle; also, that every particle is at the same distance from the centre of the disturbing force, and consequently that the displacement in each particle is equal also.

6. For the sake of illustration, let AEBD represent a sphere of iron in its non-magnetic or quiescent state, and let CM be the line on which the terrestrial magnetism is exerted from a centre of action M, which is at such a distance that the diameter of the sphere is inconsiderable in comparison with it; then every particle on its surface, and to a certain distance within it, will be acted upon by equal powers, and in directions parallel to each other, whereby the fluids in the quiescent body, before in a state of combination, will be separated in each particle; and the two fluids may now therefore be conceived to form two spherical shells $AeBd$, $Ae'Bd'$, whose centres of action will be c, c', their distances from each other being greater or less, according to the circumstances stated in No. 4.

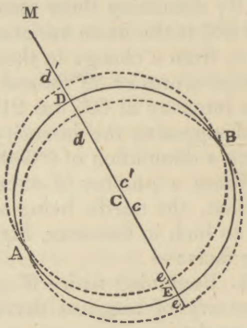

Fig. 40.

7. Therefore, in computing the action of such a mass of iron, in its temporary state of magnetism, upon a distant particle of magnetic fluid, Mr Barlow refers it to these centres, and assumes that the law of action in this, as in other cases of emanating forces, is inversely as the squares of the distance.

By means of this hypothesis Mr Barlow arrives at the following formula for the deviation Δ of a horizontal needle.

$$\text{Tan. } 7\,\Delta = \frac{\text{C}}{\text{M}} \cdot \frac{3r^2}{2d^3 \cos \delta} (2\lambda \,.\, \cos l),$$

where r = radius of the iron spheres;
d = the distance of the needle from the centre of the spheres;
λ = the complement of the magnetic latitude;
l = the complement of the magnetic longitude;
δ = the dip of the needle; and
$\frac{\text{C}}{\text{M}}$ = 1·0539 a constant quantity for cast-iron balls and shells, of every diameter, and for all distances and positions.

From this formula it necessarily follows,—

1. That though the development of the magnetism of the spheres takes place by the hypothesis only at the sur-

Action of Simple Iron Bodies on the Magnetic Needle.

face, yet the effect, as shown by the tangent of the deviation, is proportional to the cube of the diameter.

2. That the tangent of deviation is inversely as the cube of the distance.

3. That the tangent of the deviation is proportional to the sine of the double latitude and cosine of the longitude, the latter being extended from the east and west points.

These are the very laws which Mr Barlow had deduced from experiment, and he has established the correctness of his formula by comparing it with a great body of experiments made by himself and Mr Christie, and also with observations on the dipping needle.

Sect. II.—*On the Action of Simple Iron Bars and Plates on the Magnetic Needle.*

As spherical bodies possess the peculiar property of having their centre of attraction in the centre of the mass, the former becomes a fixed point whatever be the distance of the magnetic needle. As this is not the case, however, with bodies of other forms, such as bars and plates, Mr Barlow was desirous of ascertaining whether, in these cases also, the magnetic attraction of the body could be referred to the action of two centres indefinitely near to each other in the general centre of attraction of the surface of the body, viz., that point into which, if all the matter of the surface were collected, its action on the centre of the needle would be the same as the action of the whole body in its natural form.

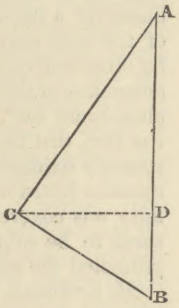

Fig. 41.

In pursuance of this plan, he supposes AB to be a bar of iron, and C the place of the needle, and, letting CD fall perpendicular on AB, he joins AC, BC. He then finds the following expression for the deviation :—

$$\tan \Delta = \mathrm{A}\,\frac{mn \cos l}{(m^2 + n^2)^{\frac{1}{4}}},$$

A being a constant quantity, l the longitude, m the force in the direction DC, and n the force in DA. In the experiments with which Mr Barlow proposed to compare this formula, the needle was placed due east and west of the bar, the longitude of its position was zero, and hence $\cos l = 1$. The formula, therefore, becomes

$$\tan \Delta = \mathrm{A}\,\frac{mn}{(m^2 + n^2)^{\frac{1}{4}}}, \text{ or } \tan \Delta \cdot \frac{(m^2 + n^2)^{\frac{1}{4}}}{mn} = \mathrm{A},$$

whatever may be the distance of the needle or its position, provided its longitude be zero.

Mr Bonnycastle's experiments.

The following experiments were made by Mr Charles Bonnycastle, with a bar 24 inches long and $1\frac{1}{4}$ inch square, inclined in the direction of the dipping needle. The magnetic needle was placed to the east and west of the bar, first opposite to its centre, and then at every 3 inches from the centre to the extremities, at the distance of 12 and 16 inches from the axis of the bar. The following were the results :—

Distance of Compass from Bar in inches.	Distance below Centre.	Observed Deviation.	Value of $\frac{mn}{(m + n^2)^{\frac{1}{4}}}$	Values of A.
16	3	2° 20′	·00240	17·03
16	6	4 25	·00438	17·62
16	9	5 45	·00563	17·88
16	12	6 0	·00596	17·63
12	3	5 20	·00484	19·28
12	6	10 0	·00899	19·62
12	9	12 0	·01152	18·45
12	12	11 30	·01160	17·54
				Mean 18·13

Influence of Magnetism on Chemical Action.

These results Mr Barlow justly regards as a further proof of the accuracy of the principles upon which his hypothesis is founded, and of his general deduction that the action of plain unmagnetized iron on a compass needle may be referred to two poles indefinitely near to each other in the common centre of attraction of the surface of the body.

Mr Bonnycastle performed another series of experiments with a plate of malleable iron 12 inches square and half an inch thick, and he obtained results almost equally accordant with Mr Barlow's hypothesis.

Sect. III.—*On the Action of Irregular Masses of Iron on the Magnetic Needle.*

Action of irregular masses of iron.

Mr Barlow was next desirous of ascertaining if the same law which applied to spheres, bars, and plates, was true in irregular masses of iron, such as a 24-pounder gun; an experiment peculiarly applicable to the object he had in view. He found that the plane of no attraction existed in the most irregular masses of iron, and the agreement between the observed deviations produced by the gun, and those calculated by his formula, was such as to satisfy him that the same laws applied to irregular as to regular masses of iron; and he was thus furnished with the means of computing the local attraction of a ship's guns upon the compass under all circumstances, and in all parts of the world.

Experiments of Mr Lecount.

These views were strikingly confirmed by several ingenious observations, made, without knowing of Mr Barlow's labours, by Mr Lecount, with bars, handspikes, mast rings, and various other iron bodies, from which he concluded "that a plane or circle held east and west (magnetic), and at right angles to the direction of the dipping needle, divides the north from the south magnetic effluvia, each lying on that side to which the dipping needle points; and by referring the position of all iron bodies to this plane, the plane of section shall divide the two into north and south polarity, provided it be of uniform thickness, or, if not, the section must be drawn through its centre of (gravity) attraction."[1]

CHAP. VII.—ON THE INFLUENCE OF MAGNETISM ON CHEMICAL ACTION.

Influence of magnetism on chemical action.

An opinion had long prevailed among philosophers that the phenomena of magnetism and electricity had a similar origin; and hence various observers had been led, previous to the discovery of electro-magnetism by Oersted, to inquire if any actions of a chemical nature could be produced by magnetism.

Experiments of Ritter.

The German philosopher Ritter was the earliest and the most active of these inquirers. He maintained that a magnetic wire, combined with another wire not magnetized, produced contractions in a frog, the south pole of the wire-magnet producing stronger contractions than the unmagnetized wire; and as he had constantly observed that the metals most susceptible of excitation excited the strongest contractions, he concluded that the south pole of a magnet has a greater affinity for oxygen than simple iron, and the north pole a less affinity. Hence he was led to confirm these views by means of several chemical reagents. He placed a magnetized wire upon pieces of glass in an earthenware dish containing weak nitric acid, when he found that the south pole was more corroded by the acid than the other, and was soon encircled with a deposition of oxygen greater than that at the other pole. In another experiment he took two flasks filled with tincture of turnsol, in one of which he placed the two south poles of two wire-magnets,

---

[1] Lecount *on the Magnetic Properties of Iron Bodies.*

Influence of Magnetism on Chemical Action.

and in the other the two north poles of two similar magnets. In the last flask the oxidation of the wires was much greater than in the first.

Experiments of Ritter.

The difference in the oxidation of the south pole was exhibited by Ritter in another way. He took three small and equal bottles filled either with pure or slightly acidulated water, and having placed in one the south pole of a wire-magnet, in another the north pole, and in the third the extremity of an unmagnetized wire of the same length, he observed that the south pole first began to deposit oxide, the unmagnetized wire next, and the north pole last. In order to exclude the access of air, the surface of the water should be covered with very fresh oil of almonds; and as light accelerates oxidation, none of the bottles should be more exposed to the sun than the rest. In support of this last observation, Ritter exposed two iron wires to the sun when placed in water, and having covered one of the bottles with black paper, he found that the wire in the uncovered bottle was oxidated more rapidly than the other.

Ritter repeated the preceding experiment with the three bottles containing an infusion of litmus in place of acidulated water. The south pole reddened the infusion most, the unmagnetic wire less, and the north pole least of all. A week is required to produce a distinct effect; and in order even to effect this, Ritter found it necessary to add as much acetic acid as would incline the infusion to red without completely changing its colour.

The following experiment of Ritter, if correctly repeated, establishes the same result. We shall give it nearly in his own words:—"Sixteen magnetic wires, of equal size and power, were placed in six vessels, all equally full of a mixture of one part nitric acid and thirty-six parts water, in the following manner: In the first glass were placed two wires, one with the north pole immersed in the fluid, the other with the south, and not more than half a line asunder; in the second, the same, but the wires an inch and three-fourths apart; in the third and fourth were each three wires, with the south poles of all immersed, but their distances in the two glasses different, as in the first and second; in the fifth and sixth were wires similarly arranged, but with the north poles immersed. Different quantities of oxide were gradually deposited, and, to express the whole in a few words, we will call the south pole S, the north pole N, their greater distance g, and their less p, and we will express the order of oxidations as follows: $SNg > SNp > 3Sp > 3Sg > 3Np > 3Ng$. On the nineteenth day it was observed that the loss of fluid by evaporation had not been equal in all the vessels, but took place in the inverse order of the oxidations. All the magnetic wires were weakened in power; NSg least, NSp more; of the wires $3Sp$, two had lost less power than the third; and in like manner $3Sg$, $3Np$, $3Ng$, had each two left more powerful than the third; the strongest were equal to NSg."

Experiments of Muschman, and Hansteen.

The next experiments on this subject were made by M. Muschman, professor of chemistry in the university of Christiania, who endeavoured to ascertain the effect of the earth's magnetism on the precipitation of silver. In his chemical course in 1817, when he was desirous of explaining the chemical theory of the tree of Diana, he took a tube like a syphon, and poured mercury into it, which accordingly occupied the lower part of the two branches: above the mercury he poured a strong solution of nitrate of silver. He then placed the two branches of the syphon so that the plane passing through them was in the magnetic meridian, and after standing a few seconds, the silver began to precipitate itself with its natural lustre; but it accumulated itself particularly in the northern branch of the syphon, while that which was less copiously precipitated in the other branch had a less brilliant lustre, and was mixed with the mercurial salt deposited from the solution. M. Muschman and Professor Hansteen repeated this experiment in an improved form with the very same result. On this occasion they used simultaneously two syphons prepared in the same manner, the one being placed in the direction of *north* and *south*, and the other in that of *east* and *west*. The silver began to precipitate itself in the direction of *north* and *south*, and it particularly raised itself in the *north* branch with a lustre more brilliant than in the *south* one; whereas in the syphon whose plane lay *east* and *west*, *no change had taken place even at the end of twelve hours.* Hence the two Norwegian philosophers concluded, with some reason, that the magnetism of the earth had an influence on the precipitation of silver from a solution of its nitrate; and M. Muschman inferred, from the experiment, the identity of galvanism and magnetism. He regarded every dissolution as the result of a galvanic effect, the precipitated metal carrying off the electricity set at liberty, and carrying itself, in order to be disengaged, to the place where it could find the opposite electricity, which was the north pole. M. Muschman considered this hypothesis confirmed by the geological fact, that at Königsberg silver was found in the metallic form, stretching from north to south; and the presence of the silver is always indicated by a certain quantity of pyrites and blendes. Hence he conceived that the silver had been insensibly united to sulphur, and that by the effect of the earth's magnetism alone it had been carried towards the copper and the zinc.

Laws of Magnetic Forces, &c.

Experiments of Fresnel;

M. Fresnel made a series of experiments with the view of decomposing water by the magnet. He proposed to produce an electric current in an electro-magnetic helix inclosing a bar-magnet covered with silk. The two ends of the wire were plunged in slightly acidulated water, and he observed very decided effects; but there were so many anomalies in the result, which he could not explain, that he abandoned the inquiry. He was particularly struck with the fact, that the wire which should be the positive one was strongly oxidated, whilst the other extremity preserved its metallic lustre during a whole week. The negative extremity was covered with a saline deposit, which he conjectured to be sulphate of lime, and which he supposed had protected the wire from oxidation.

of Erdmann.

M. Erdmann, after a very elaborate inquiry into the effects of magnets as chemical agents, came to the conclusion that the observed phenomena were due to the influence of other causes, which had not been sufficiently guarded against.

A curious fact, connected perhaps with the class of phenomena under our observation, was noticed by M. Lebaillif. He observed that the poles of a magnetic needle delicately suspended were repelled by pieces of antimony or bismuth that were brought near them.

CHAP. VIII.—ON THE LAWS OF THE MAGNETIC FORCES, THE MUTUAL ACTION OF MAGNETS, AND MAGNETIC CURVES.

SECT. I.—*On the Law of the Magnetic Force.*

Law of the magnetic force.

In our history of magnetism we have given very full details of the various attempts which were made by philosophers to determine the law according to which the intensity of the attractive and repulsive power of magnets varied with the distance at which these forces were exerted. Like all other laws, an approach to the discovery of it had been made by various philosophers; but the merit of its perfect establishment undoubtedly belongs to Dr Robison and Coulomb, the last of whom placed it beyond the reach of doubt. The difficulties which were to be overcome in this inquiry arose from the invariable co-existence of two opposite polarities in each of the two bodies whose mutual action was under examination; and this difficulty was increased from these polarities not being concentrated in particular points, but diffused in an unequal degree over each half of the magnet and the needle.

Researches of Coulomb

In this delicate inquiry Coulomb employed two methods. In the first he suspended a magnetic needle by a silk fibre, and when it was in the magnetic meridian, he presented to it at different distances another magnetic needle, and determined by observation and calculation the force with which they acted upon each other at these distances. A needle an inch long, weighing 70 grains, and magnetized to saturation, was suspended by a fibre of silk three lines long, and a steel-wire magnet 25 inches long was placed vertically in the magnetic meridian at different distances, so that its south pole was always ten lines below the northern extremity of the suspended needle. The needle was now made to oscillate when the magnet was at different distances from it, and the following were the number of oscillations in 60^s, the number being fifteen when the magnet was removed, and the needle influenced only by the magnetism of the earth.

Distance of a Wire-Magnet from the middle of the Needle.	Number of Oscillations in 60 seconds.
4 inches	41
8 ditto	24
16 ditto	17

By means of the formula for the pendulum, in which the forces are in the direct ratio of the square of the number of oscillations performed in the same time, Coulomb has computed their intensity. As all the forces concerned are in the plane of the magnetic meridian, the force which produces the horizontal oscillations depends on the parts of these forces which are decomposed in a horizontal direction. Now Coulomb had demonstrated that the magnetic fluid might be considered as concentrated at a point 10 lines from the extremity of the wire-magnet; but as the suspended needle was 1 inch long, its north pole was attracted at the distance of $3\frac{1}{2}$ inches, and its south pole at the distance of $4\frac{1}{2}$ inches, so that 4 inches was the mean distance at which, in the first experiment, the lower pole of the wire-magnet exerted its action on the two poles of the needle. In the second experiment the mean distance was 8 inches. But as the horizontal force which produces the oscillations is the square of the number performed in 60^s, the magnetic force of the earth will be 15^2, and the combined forces of the earth and the wire-magnet will, in the first, second, and third experiments, be 41^2, 24^2, and 17^2, so that the forces which emanate from the wire-magnet will be 41^2-15^2, 24^2-15^2, 17^2-15^2, whence we deduce the following results:—

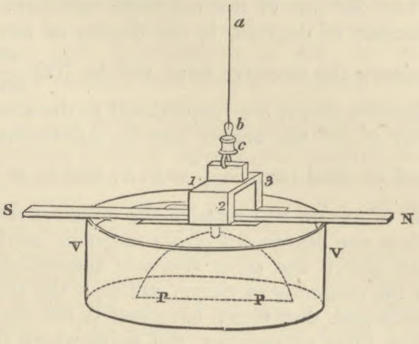
Mean Distance.	Force depending on the Action of the Wire-magnet.
1*st* experiment 4 inches	$41^2-15^2=1456$
2*d* experiment 8 ditto	$24^2-15^2=351$
3*d* experiment 16 ditto	$17^2-15^2=64$

The distances in the first and second experiments being as one to two, the variation of the force would have been exactly as the squares of these numbers had the force in the second experiment been 364 instead of 351; and the same would have been the case had the force in the second and third experiments been 332 and 83, instead of 351 and 64. This difference, therefore, requires to be investigated. Coulomb has accounted for it, and calculated the correction for these numbers in the following manner. In the experiments the action of the superior pole of the wire-magnet was neglected. The distance of its inferior pole from the centre of the needle was 16 inches, and the distance of the superior pole from the centre of the needle is nearly $\sqrt{(16^2+23^2)}$, so that the force of the former is to that of the latter nearly as 100 to 19. Hence, as the oscillations of the needle are produced by the action of these two poles, which exert their force in opposite directions, the square of the number of oscillations which the single action of the inferior pole of the magnet would produce, should be diminished $\frac{18}{100}$ths by the opposite action of the superior pole; so that 64 is only the excess of the real amount of the single action of the lower part of the magnet over $\frac{18}{100}$ths of the number which represents it. The true value will therefore be 79. The true intensities of the forces will, at the distances 4, 8, and 16 inches, be 1456, 351, and 79, or nearly in the inverse ratio of the squares of the distances.

M. Coulomb has in like manner demonstrated, that the repulsive force of similar poles follows the same law of the distance.

Coulomb's magnetic balance.

The *second* method employed by Coulomb requires the use of the magnetic balance, which is represented in figs. 42 and 43, which is a modification of the torsion balance already described in our article on ELECTRICITY. The suspending wire *ab*, fig. 42, carries at its lower extremity a pair of pincers *c*, which holds a stirrup 1, 2, 3, formed of a plate of very light copper. In this stirrup is placed a small piece of card covered with a coat of Spanish wax, on which is impressed the mark of the wire or bar of steel SN to be used, in order that it may always be put in the same position. Under the middle of the stirrup is fixed a vertical plane PP, wholly immersed in a vessel VV of water, the resistance of which may quickly stop the oscillations of the needle or magnet SN in the stirrup. When fitted up for the experiments under our consideration, the apparatus shown in fig. 42 is placed in a square box AB (see fig. 43), 3 feet wide and 18 inches high. At the height of 9 inches above the bottom is placed a horizontal circle of wood or copper, 2 feet 10 inches in diameter, and divided into degrees. On this box is placed a cross piece CD, which supports at its middle point a tube EF, 30 inches long, and terminating in a torsion micrometer at M. The pincer of this micrometer holds the upper end of a brass wire, to the other extremity of which is adapted a ring of copper intended to carry a steel needle.



Fg. 42.

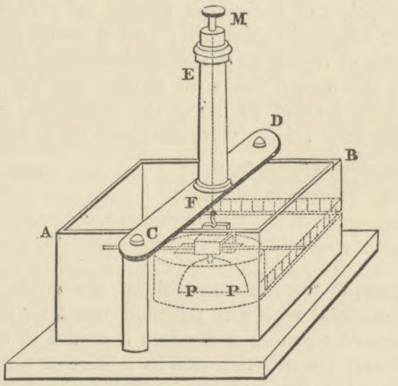


Fig. 43.

Before the commencement of the experiment, the box AB is placed so that the direction of the magnetic meridian passes through the divisions *zero* and 18° of the horizontal circle. The next step is to place in the stirrup a well magnetized steel needle NS, of a rectangular form, and to adjust the torsion micrometer M, so that the torsion of the wire is nothing when the needle NS is in the magnetic meridian, or that the magnetic meridian passes through the *zero* on the scale of the torsion micrometer. In the direction of the magnetic meridian a vertical ruler of wood or copper, 1 or 2 lines thick, is fixed, so that the end of the needle may come against it when it is in the magnetic meridian.

Coulomb now took two wire magnets 24 inches long and $1\frac{1}{2}$ in diameter, and he placed one of them in the stirrup, as at NS, and determined the force with which the magnetism of the earth drew it back into the magnetic meridian. For this purpose he twisted the suspending wire *ab* through

Laws of Magnetic Forces, &c.

two circles or circumferences, minus 20°, till the needle stopped 20° from the magnetic meridian, so that, considering the forces as nearly proportional to the arcs (when the angle is about 20°), about 35° of torsion were necessary to keep the magnetic needle one degree out of the magnetic meridian. The two circles of torsion, *minus* 20°, are equal to $2 \times 360° - 20° = 700°$; the degrees of torsion required to keep the needle 20° out of the magnetic meridian, or 700° of torsion, are a measure of the directive force of the needle when 20° out of the magnetic meridian. For any other number of degrees, δ, the degree of torsion necessary to balance the directive force will be $700 \frac{\sin \delta}{\sin 2°}$, because the directive forces are proportional to the sines of the angles. But at 20° the angles may be substituted for the forces, and we shall have $\frac{700\,\delta}{20} = 35\,\delta$; that is, as we stated above, 35° of torsion will balance the directive force of the needle when one degree out of the magnetic meridian. Coulomb now placed the other similarly magnetized wire vertically in the magnetic meridian, so that if the two wires had been prolonged, they would have met at the distance of *ten* lines from their extremities, the point where the magnetism of each acts as if it were concentrated there. He placed the similar poles of each opposite to each other, and consequently the horizontal needle or wire was repelled out of the magnetic meridian; and it took a position at which the force of repulsion of the vertical needle or wire was balanced by the united forces of torsion and the earth's magnetism, which tended to bring the horizontal wire to rest. The following results were obtained after different trials:—

Circles of Torsion given to the suspending wire by the Torsion Micrometer.	Observed Angles of Repulsion.
0	24
3	17
8	12

Now, in the first experiment, the angle through which the horizontal wire was repelled was 24°, reckoning from the zero of torsion; and when it rested in this position, it was driven towards the zero by a force of torsion of 24° *plus* the directive force of the earth's magnetism, which being 35° for every 1°, amounts to $24 \times 35° = 840°$. The total repulsive force was therefore $840° + 24° = 864°$.

In the second experiment the torsion micrometer was turned round *three* circles, in a direction opposite to the 24° first produced; but notwithstanding this great torsion, the horizontal wire-magnet, repelled by the vertical one, returned only to 17° from the magnetic meridian. The force of torsion was therefore 3 circles $+ 17° = 1097°$: but the directive force for 17° is $17 \times 35° = 595°$, hence we have for the total repulsive force $1097° + 595° = 1692°$.

In the third experiment the torsion micrometer was turned round eight circles, and the wire magnet stopped at 12° from the magnetic meridian. The force of torsion was therefore 8 circles $+ 12° = 2892°$; but the directive force for 12° is $12 \times 35° = 420°$, hence we have for the total repulsive force $2892° + 420° = 3312°$.

As the arcs of repulsion are in these experiments so small, we may safely reckon them equal to their chords, and we obtain the following results:—

Distances at which the Repulsive Force is exerted.	Corresponding Repulsive Forces in Degrees of Torsion.
12	3312°
17	1692
24	864

Assuming 3312° as correct, the other numbers ought to have been 1650 and 828 instead of 1692 and 864, if the force varies inversely as the square of the distance. The differences 42° and 36° correspond nearly with a degree of error in the observed position of the moveable steel wire, since the directive force is 35° for every degree of deviation from the magnetic meridian. Such an error is certainly a very small one in experiments of this kind, and we therefore conclude that the attractive and repulsive forces of magnets decrease as the squares of their distances increase.

Had the experiments been made upon magnetic points, such an error would not have existed; but they were made with forces diffused over portions of the wire-magnet of some extent. In the last experiment (M. Biot remarks) "when the two wires were nearest each other, the influence of the points lying near the intersection was more weakened by obliquity than in the other experiment; or, in other words, there were at equal obliquities more points which acted in the greater distances (24 and 17) than in the smaller one (12). But as we did not take this augmentation into account, we ought to find that the repulsive force observed at the smaller distance, being reduced in the ratio of the square of the distance, gives for larger distances repulsive forces a little more feeble than those which were actually observed."

In the first method of observation, Coulomb was obliged to calculate the effect of the distant pole; but in the present method this was unnecessary, as the wire magnets were 2 feet long, and the greatest arc of repulsion, viz. 24°, corresponded to a distance of 5 inches between the repelling poles. The other poles were therefore at least four times more distant than those whose repulsive action was calculated; their direct action was therefore 16 times weaker, besides being greatly weakened by the extreme obliquity with which it acted. Had the wire magnets been shorter, the action of all the poles might have been taken into consideration.

Laws of Magnetic Forces, &c.

SECT. II.—*On the Mutual Action of Magnets.*

Mutual action of magnets.

We have already seen, from Professor Barlow's experiments on spheres and bars of soft iron, that they act upon needles, whether temporarily or permanently magnetized, as if their magnetism emanated from the centre of their surface, or from two points indefinitely near to each other. This, however, is not the case with permanent magnets, in which the magnetic force is concentrated in poles considerably distant from each other.

CASE 1. When the needle or a small magnet is placed in the line joining the poles of the other magnet.—In considering the mutual action of magnets, we shall suppose the larger one NS to be fixed, and the smaller one *ns* to have the form of a needle, moveable in a horizontal plane round the pivot in its centre A, B, or C. Let the needle then be placed at A, with its centre A in the line SN prolonged, and let us suppose that the magnetic forces emanate from points N, S; *n*, *s*, being the analogous poles of the needle. The north pole N of the magnet *attracts* the *south* pole *s* of the needle with a force inversely proportional to the square of N*s*, and *repels* the *north* pole *n* with a force inversely proportional to the square of N*n*. The effect of both of these forces is to bring *s* as near as possible to N, and to remove *n* as far as possible, that is, to place the needle in the same straight line as NS, as shown in fig. 44.

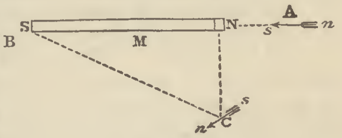

Fig. 44.

CASE 2. Let the needle *ns* be now placed at B, fig. 45, so that its centre B is anywhere in the direction of a right line MB perpendicular to the middle M of the magnet. When the centre of the needle is placed above M, it is quite clear that it will stand with its north pole *n* towards the south pole S of the magnet, and its south pole *s* towards the pole N. When the needle is removed to B, the same thing will happen; S will attract *n* with a force equal to *nb*, while N repels *n* with a force *nc*, a little less than *nb*, on account of the increase of distance. The result of these will be the

Laws of Magnetic Forces, &c.

force *na*, in the diagonal of the parallelogram *ncab*. In the same manner, the pole N will attract *s* with a force *es*, and the pole S will repel *s* with a less force *fs*, the resultant of which is *sg*; but as the poles S, N are equally strong, and act at equal distances upon the needle, the resulting force *an* must be equal to *gs*, and the needle will remain in that position, which is parallel to the axis SN of the magnet.

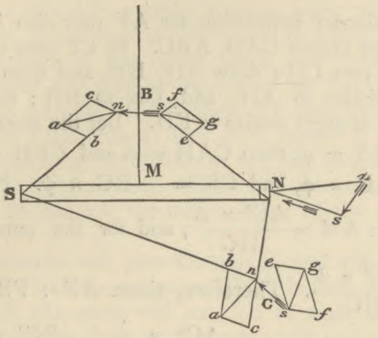

Fig. 45.

Case 3. When the centre of the needle is placed in an intermediate position, as at C, fig. 45, neither in the axis NS, nor in the perpendicular MB, it will take an intermediate position, which may be thus found. Its north pole *n* is shown in the figure as directed to the centre M of the magnet; but it cannot remain in this position; N repels *n* with a force equal to *nc*, and S attracts it with a force *nb* smaller than *nc*, from the greater distance. The resultant of these is *na*, which is very different from *ns*. For the same reason, the south pole *s*, repelled by S with a force *sf*, and attracted by N with a force *se*, will have a tendency to move in the direction *sg*, nearly equal and opposite to each other; it will therefore take a position *ns*, fig. 45, nearly at right angles to its former position. It will rest therefore in its new position with its north pole towards N, and its south pole towards S.

If we project upon paper the magnet and the needle placed in different positions, and make the forces of each pole of the magnet on each pole of the needle inversely proportional to the squares of the distances, it will be easy to find the position in which the needle will rest at any distance from the magnet, and at any position of its centre with regard to the axis of the magnet.

When a needle is exposed to the combined action of two magnets, as shown in the annexed figure, the phenomena, though capable of calculation by the principles already explained, are extremely perplexing and complicated when studied experimentally. Dr Robison, who first discovered and explained these phenomena, has given such an interesting account of them, that we shall make use of his description of the phenomena, leaving the explanation of them to the next section on magnetic curves.

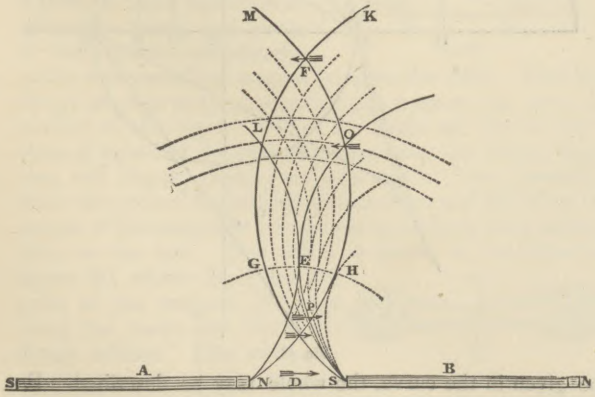

Fig. 46.

Laws of Magnetic Forces, &c.

"Two large and strong magnets, A and B, were placed with their dissimilar poles fronting each other, and about three inches apart. A small needle, supported on a point, was placed between them at D, and it arranged itself in the same manner as the great magnets. Happening to set it off to a good distance on the table, as at F, he was surprised to see it immediately turn round on its pivot, and arrange itself nearly in the opposite direction. Bringing it back to D, restored it to its former position. Carrying it gradually out along DF, perpendicular to NS, he observed it to become sensibly more feeble, vibrating more slowly; and when in a certain point E, it had no polarity whatever towards A and B, but retained any position that was given it. Carrying it farther out, it again acquired polarity to A and B, but in the opposite direction; for it now arranged itself in a position that was parallel to NS, but its north pole was next to N, and its south pole to S.

"This singular appearance naturally excited his attention. The line on which the magnets A and B were placed had been marked on the table, as also the line DF, perpendicular to the former. The point E was now marked as an important one. The experiments were interrupted by a friend coming in, to whom such things were no entertainment. Next day, wishing to repeat them to some friends, the magnets A and B were again laid on the line on which they had been placed the day before, and the needle was placed at E, expecting it to be neutral. But it was found to have a considerable verticity, turning its north pole towards the magnet B; and it required to be taken farther out towards F before it became neutral. While standing there, something chanced to joggle the magnets A and B, and they instantly rushed together. At the same instant the little magnet or needle turned itself briskly, and arranged itself, as it had done the day before at F, quivering very briskly, and thus showing great verticity. This naturally surprised the beholders; and he now found, that by gradually withdrawing the magnets A and B from each other, the needle became weaker, then became neutral, and then turned round on its pivot, and took the contrary position. It was very amusing to observe how the simply separating the magnets A and B, or bringing them together, made the needle assume such a variety of positions, and degrees of vivacity in each.

"The needle was now put in various situations in respect to the two great magnets, namely, off at a side, and not in the perpendicular DF. In these situations it took an inconceivable variety of positions, which could not be reduced to any rule; and in most of them it required only a motion of one of the great magnets for an inch or two, to make the needle turn briskly round on its pivot, and assume a position nearly opposite to what it had before."

In the preceding observations, the action of the one magnet tended only to change the direction of the other, and this change is clearly produced by the sum of the actions of the two poles of the magnet; for while the one pole tends to draw the one half of the needle into its position of equilibrium, the other pole repels the other half into the same position. The force, therefore, which thus acts upon a needle, is called the *directive force* of a magnet.

The *attractive force* of a magnet is, on the other hand, equal to the difference of the two forces exerted by its poles on the needle; and when the two forces happen to be equal, the attractive force will be nothing, and the needle will have no tendency to approach the magnet, though the directive power of the latter may be very great. This will be understood from fig. 45, when the needle *ns* is at right angles to the axis of the magnet. The attraction of the pole N for *s* is equal to its repulsion of *n*, and these two forces will neutralize each other, so as to prevent any ten-

Laws of Magnetic Forces, &c.

dency to approach N, even if the needle *ns* were free to do it. On the other hand, in fig. 44, where the needle at C has its south pole *s* more attracted by N than its north pole *n* is repelled by it, the predominance of the attraction would carry the needle towards N if it were at liberty. These views explain the well-known fact, that a needle floated on a piece of cork quickly places itself in the magnetic meridian; but it never will approach the north side of the vessel. In order to explain this fact, Dr Gilbert asserted that the directive power of a magnet extended much farther than its attractive power; a mistake which arose from his not having observed the effects of the simultaneous action of the four poles of the magnets which acted upon each other.

SECT. III.—*On Magnetic Curves.*

Magnetic curves.

The name of magnetic curves has been given to those curves into which an infinite number of very minute needles would arrange themselves when placed round a magnet, and at liberty to move round an axis. A rude idea of these curves is given by the appearance of iron filings when scattered upon a sheet of paper, and agitated immediately above a magnet.

The action of a magnet upon a needle is greatly simplified when the needle is so small that its two poles may be considered as coincident; in which case the difference between the action of any one pole of a magnet upon them will be infinitely small. When this is the case, the directive force of the magnet upon the small needle must be very considerable, while the attractive force, measured by the difference of the action on the two poles, is nothing. Hence it is that alone which is concerned in the arrangement of minute needles or particles subjected to the action of a magnet.

An investigation of the force of the magnetic curves was made by Professor Playfair, at the request of Professor Robison. Professor Leslie afterwards undertook the same investigation;[1] and Dr Roget[2] more recently gave a more simple demonstration of the two fundamental propositions respecting them, and described an instrument which he invented for the mechanical description of these curves. Playfair's investigation, which is sufficiently simple, is as follows; the only change which we have made upon it being the substitution of the second power of the distance for the *m*th power as used by him.

PROP. Two magnetical poles being given in position, the force of each of which is inversely as the square of the distance from it, it is required to find a curve, in any point of which a needle (indefinitely short) being placed, its direction, when at rest, may be a tangent to the curve.

"1. Let A and B be the poles of a magnet, C any point in the curve required; then we may suppose the one of these poles to act on the needle only by repulsion, and the other only by attraction, and the direction of the needle when at rest will be the diagonal of a parallelogram the sides of which represent these forces. Therefore, having joined AC and BC, let AD be drawn parallel to BC, and make $\frac{1}{AC^2} : \frac{1}{BC^2} = AC : AD$; join CD, then CDF will touch the curve in C.

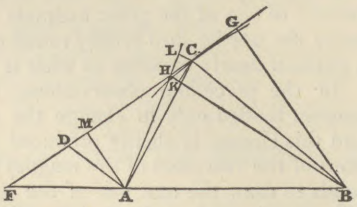

Fig. 47.

"2. Hence an expression for AF may be obtained; for, by the construction, $AD = \frac{AC^3}{BC^2}$; and since $BC : AD = BF : FA$, and $BC - AD : AD = AB : AF$, we have $AF = \frac{AB \times AC^3}{BC^3 - AC^3}$.

"3. A fluxionary expression for AF may also be found in terms of the angles CAB, ABC. In CF take the indefinitely small part CH; draw AH, BH, and from C draw CL perpendicular to AH, and CK to BH; draw also BG and AM at right angles to FH. Let the angles CAB $= \phi$ and CBA $= \psi$, then CAH $= \dot{\phi}$ and CBH $= -\dot{\psi}$; also $CL = AC \times \dot{\phi}$, and $CK = -BC \times \dot{\psi}$. Now $HC : CL = AC : AM = \frac{AC^2 \times \dot{\phi}}{HC}$; and for the same reason $BG = -\frac{BC^2 \times \dot{\psi}}{HC}$. Therefore, since $AF : FB = AM : BG$, we have $AF : FB = \frac{AC^2 \times \dot{\phi}}{HC} : -\frac{BC^2 \times \dot{\psi}}{HC}$, and $AF : AB = \sin \dot{\psi}^2 \dot{\phi} : -\sin \psi^2 \dot{\phi} - \sin \phi^2 \dot{\psi}$; wherefore, if $AB = a$, $AF = \frac{-a\dot{\phi} \sin \dot{\psi}^2}{\dot{\psi} \sin \varphi^2 + \dot{\phi} \sin \psi^2}$.

"4. If this value of AF be put equal to that already found, a fluxionary equation will be obtained, by the integration of which the curve may be constructed. Because $AF = \frac{AB \times AC^3}{BC^3 - AC^3}$; and since $AC = \frac{a \sin \psi}{\sin (\dot{\phi} + \psi)}$, and

$$BC = \frac{a \sin \phi}{\sin (\phi + \psi)}, \text{ we have by substitution}$$

$$AF = \frac{a \sin \psi^3}{\sin \phi^3 - \sin \psi^3} = -\frac{a \dot{\phi} \sin \psi^2}{\dot{\psi} \sin \phi^2 + \dot{\phi} \sin \psi^2}.$$

Hence $\sin \phi^2 \times \dot{\psi} \sin \psi^3 + \dot{\phi} \sin \psi^5 = -\sin \psi^2 \times \dot{\phi} \sin \phi^3 + \varphi \sin \psi^5$, and therefore $\dot{\psi} \sin \psi + \dot{\varphi} \sin \varphi = 0$, and $\cos \varphi + \cos \psi = C$.

"5. Hence, if, besides the points A and B, any other point be given in the curve, the whole may be described. For instance, let the point E be given in the curve, and in the line DE which bisects AB at right angles. Describe from the centre A a circle through E, viz. QER; then AD be-

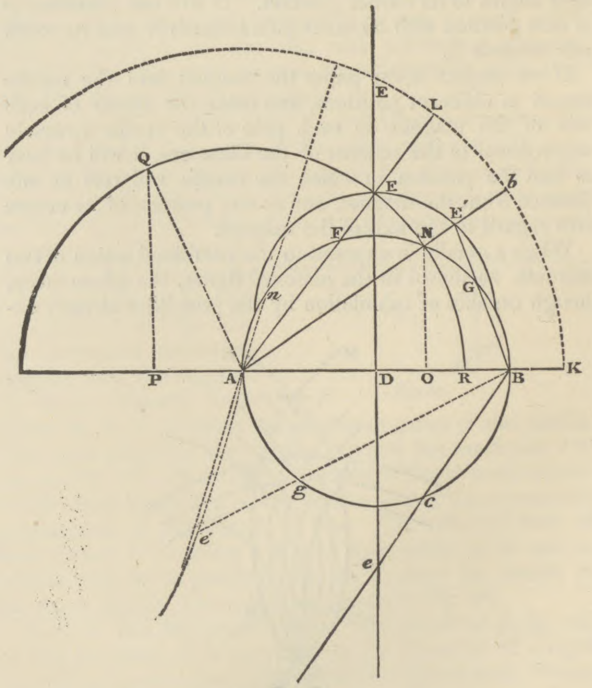

Fig. 48.

Laws of Magnetic Forces, &c.

---

[1] *Geometrical Analysis.*

[2] *Journal of the Royal Institution of Great Britain,* vol. i., p. 311. Feb. 1831.

Laws of Magnetic Forces, &c.

ing the cosine of DAE to the radius AE, the sum of the cosines of $\varphi \times \psi$ will be everywhere (to the same radius) = 2 AD = AB. Therefore, to find E′, the point in which any other line AN, making a given angle with AB, meets the curve, draw from N, the point in which it meets the circumference of the circle QER, NO perpendicular to AB, so that AO may be the cosine of NAO, and from O toward A take OP = AB, then AP will be the cosine of the angle ABE′; so, to find BE′, draw PQ perpendicular to AP, meeting the circle in Q; join AQ and draw BE′ parallel to AQ, meeting AE′ in E′; the point E′ is in the curve. In this way the other points of the curve may be found.

"The curve will pass through B, and will cut AB at an angle of which the cosine = RB. If then E be such that AE = AB, the curve will cut AB at right angles. If E″ be more remote from A, the curve will make with AB an obtuse angle toward D; in other cases it will make with it an acute angle.

"A construction somewhat more expeditious may be had by describing the semicircle AFB, cutting AE in F, and AE′ in N, and describing a circle round A with the distance AL = 2 AF, cutting AE′ in *b*. If BG be applied in the semicircle AFB = N*b*, BG must cut AN in a point E′ of the curve, because AN + BG = 2 AF, and AN and GB are cosines of the angles at A and B.

"As the lines AN and BG may be applied either above or below AB, there is another situation of their intersection E′. Thus A*n* being applied above, and B*g* below, the intersection is in *e*′. The curve has a branch extending below A; and if D*e* be made = DE, and B*e* be drawn, it will be an asymptote to this branch. There is a similar branch below B. But these portions of the curve evidently suppose an opposite direction of one of the two magnetic forces, and therefore have no connection with the position of the needle."[1]

The general form of the magnetic curves is shown in fig. 49, where they are seen *converging* to the two poles N, S of the magnet NS, and changing their form with their distance from the magnet.

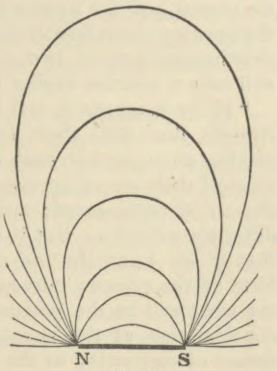

Fig. 49.

We have already stated that iron filings, arranged by the action of a powerful magnet, afford the finest experimental illustration of the magnetic curves. The best way to do this is to stretch a sheet of paper tightly over a wooden frame, and place it horizontally immediately above a powerful bar magnet lying on the table. Fine iron filings are now to be shaken through a gauze bag upon the surface of the paper. When the filings are thrown into a state of agitation by gently tapping upon the paper frame, they will dispose themselves into regular lines, stretching from one pole of the magnet to the other, and following the course of the magnetic curves, and exhibiting them beautifully to the eye. This effect is shown in the annexed figure 50, where N, S are the poles of the magnet NS, *mn* being the mean line where no filings adhere. The same arrangement is also produced when the magnet is held above the paper containing the filings.

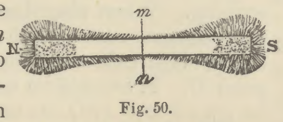

Fig. 50.

In the case of induced magnetism, the steel filings arrange themselves in curves round the iron on which the magnetism is induced, as shown in fig. 51, where the small bar of iron is in contact with the north pole N of a magnet, *mn* being the mean line which separates the two opposite actions of the little iron bar. When the little bar of iron is placed at a distance from the magnet N, as in fig. 52, the filings arrange themselves as in that figure, *mn* being the mean line as before.

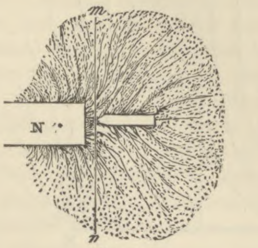

Fig. 51.

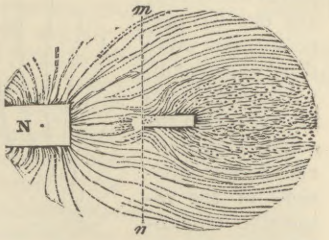

Fig. 52.

Dr Roget gives the following interesting account of the phenomena which take place by continuing to agitate the filings when they are arranged, as in fig. 53:—

"By continuing to tap upon the paper," says he, "the filings arrange themselves still more visibly into separate lines; but here a curious and perhaps unlooked-for phenomenon presents itself. The lines gradually move and recede from the magnet, appearing as if they were repelled instead of attracted, as theory would lead us to expect. This arises from the circumstance, that each particle of iron, or cluster of particles, is thrown up into the air by the shaking of the paper, and, while unsupported, immediately turns on its centre, and acquires a position more or less oblique to the plane of the paper. This is shown in fig. 53, in which M represents a section of the magnet, PP a section of the paper, and *ff* the position of the filaments of iron thrown up into the air. The end of each filament nearest to the magnet is thus turned a little downwards, and the filament falls upon the paper at a point a little more distant than that which it before occupied; and thus, step by step, it moves farther and farther from the magnet, till it reaches the edge of the paper, and falls off.

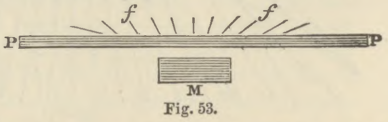

Fig. 53.

"When the magnet, instead of being beneath the paper, is held above it, the effect is just the reverse. In this latter case, the lower ends of the filaments having a tendency to turn towards the magnet, the filings gradually collect under it, when made to dance by the vibrations of the paper, instead of falling outwards as they did before. This will be seen from fig. 54, where the letters have the same indications as in fig. 53."[2]

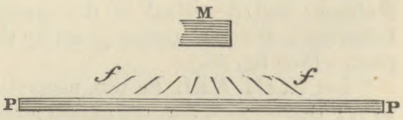

Fig. 54.

A different set of magnetic curves is produced when two similar poles, for example, two north poles, as shown in fig. 55, are placed near each other. These curves are called *divergent* curves, and may be exhibited by iron filings like the convergent ones.

Dr Roget has given the following expeditious method of delineating a great number of magnetic curves, related to the same distance between two magnetic poles. He describes from each pole N, S, fig. 56, as centres, the equal circles or semicircles AA, BB, with as large a radius as the paper will allow; and dividing the axis produced till

---

Laws of Magnetic Forces, &c.

it meets both circles, he marks off, on the circumferences of both circles, the points where they are cut by perpendiculars from these points of division; then drawing radii from the centre of each circle to the divisions of the respective circumferences, the mutual intersections of these radii will give different sets of points indicating the form of the magnetic curves which pass through them. These curves are, in the present case, composed of a succession of diagonals of the lozenge-shaped interstices formed by the intersecting radii, as shown from *convergent* curves in the upper half of the figure. In the case of *divergent* curves in fig. 55, we must take the other diagonals of the lozenge-shaped intervals between the intersecting radii; that is, the diagonals which cross those constituting the convergent curves. This is shown in the lower half of the figure.

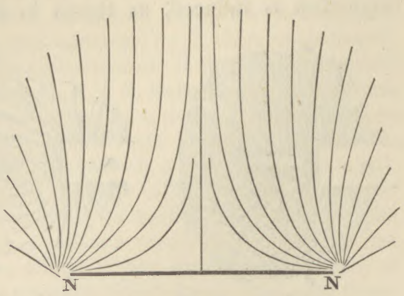

Fig. 55.

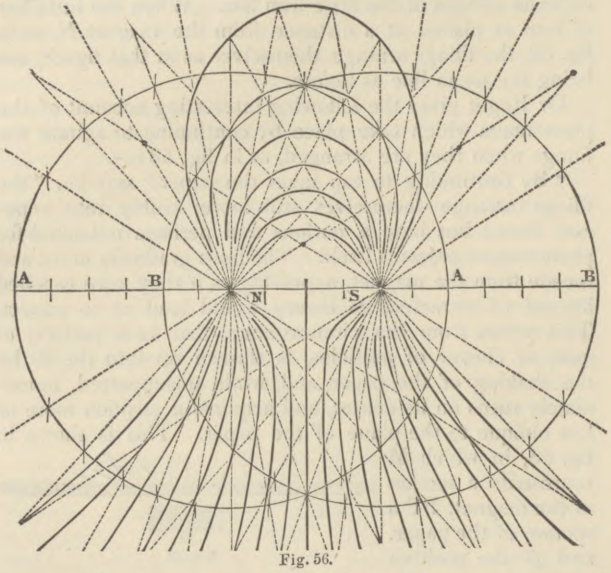

Fig. 56.

The curves which are formed when the north and south poles of two magnets are placed near each other, as in fig. 56, enable us to explain the phenomena discovered by Dr Robison, and described in the preceding section. The following is the explanation given by that eminent philosopher. (See fig. 46.)

"Let NHM, NEL, be two magnetic curves, belonging to A; that is, such that the needle arranges itself along the tangent of the curve. Then the magnet B has two curves SGK, SEI, perfectly equal, and similar to the other two. Let the curves NHM and SGK intersect in C and F. Let the curves NEL and SEI touch each other in E.

"The needle being placed at C, would arrange itself in the tangent of the curve KGS, by the action of B alone, having its north pole turned towards the south pole S of B. But, by the action of A alone, it would be a tangent to the curve NHM, having its north pole turned away from N. Therefore, by the combined action of both magnets, it will take neither of these positions, but an intermediate one, nearly bisecting the angle formed by the two curves, having its north pole turned toward B.

"But remove the needle to F. Then, by the action of the magnet A, it would be a tangent to the curve FM, having its north pole toward M. By the action of B, it would be a tangent to the curve KFG, having its north pole in the angle MFG, or turned toward A. By their joint action, it takes a position nearly bisecting the angle GFM, with its north pole toward A. Let the needle be placed in E. Then, by the action of the magnet A, it would be a tangent to the curve NEL, with its north pole pointing to F. But, by the action of B, it will be a tangent to SEI, with its north pole pointing to D. These actions being supposed equal and opposite, it will have no verticity, or will be neutral, and retain any position that is given to it.

Laws of Magnetic Forces, &c.

"The curve SEI intersects the curve NHM in P and Q. The same reasoning shows that when the needle is placed at P, it will arrange itself with its north pole in the angle SPH; but, when taken to Q, it will stand with its north pole in the angle EQM.

"From these facts and reasonings we must infer, that, for every distance of the magnets A and B, there will be a series of curves, to which the indefinitely short needle will always be a tangent.

"They will rise from the adjoining poles on both sides, crossing diagonally the lozenges formed by the primary or simple curves, as in fig. 46. These may be called compound or secondary magnetic curves. Moreover, these secondary curves will be of two kinds, according as they pass through the first or second intersections of the primary curves, and the needle will have opposite positions when placed on them. These two sets of curves will be separated by a curve GEH, in the circumference of which the needle will be neutral. This curve passes through the points where the primary curves touch each other. We may call this *the line of neutrality*, or inactivity.

"We now see distinctly the effect of bringing the magnets A and B nearer together, or separating them farther from each other. By bringing them nearer to each other, the point E, which is now a point of neutrality, may be found in the *second* intersection (such as F) of two magnetic curves, and the needle will take a sub-contrary position. By drawing them farther from each other, E may be in the *first* intersection of two magnetic curves, and the needle will take a position similar to that of C.

"If the magnets A and B are not placed so as to form a straight line with their four poles, but have their axes making an angle with each other, the contacts and intersections of their attending curves may be very different from those now represented; and the positions of the needle will differ accordingly. But it is plain from what has been said, that if we knew the law of action, and consequently the form of the primary curves, we should always be able to say what will be the position of the needle. Indeed, the consideration of the simple curves, although it was the means of suggesting to the writer of this article the explanation of those more complicated phenomena, is by no means necessary for this purpose. Having the law of magnetic action, we must know each of the eight forces by which the needle is affected, both in respect of direction and intensity; and are therefore able to ascertain the single force arising from their composition.

"When the similar poles of A and B are opposed to each other, it is easy to see that the position of the needle must be extremely different from what we have been describing. When placed anywhere in the line DF, between two magnets, whose north poles front each other in N and S, its north pole will always point away from the middle point D. There will be no neutral point E. If the needle be placed at P or Q, its north pole will be within the angle EPH, or FQI. This position of the magnets gives another set of secondary curves, which also cross the primary curves passing diagonally through the lozenges formed by their intersection. But it is the other diagonal of each lozenge which is a chord to those secondary curves. They

Terrestrial Magnetism.

will therefore have a form totally different from the former species."

CHAP. IX.—ON TERRESTRIAL MAGNETISM.

We have already seen, in preceding chapters, that a magnetic bar or needle, when either suspended by a thread, or at liberty to move freely upon a pivot, will, when all other magnetic bodies are entirely removed from it, settle in a fixed position, which, in this country, is about 25° to the W. of N.; this deviation of the needle from the N. is called its *variation* or *declination.* The very same thing will take place if a magnet or magnetized needle is placed on a piece of cork, and made to float on any fluid surface. The magnetic force by which the magnetic needle is thus made to take a fixed direction, and to return to it when it is pushed aside from that direction, has been naturally supposed to reside in the earth, and hence it has been called *terrestrial magnetism.*

But not only is a magnetized body *directed* in this manner by some unseen power; an unmagnetized body, such as a piece of iron, may be rendered permanently magnetic by the same power. This phenomenon is said to have been first observed in the vertical rod of the weather-cock of the church of the Augustines at Mantua, though others have ascribed the discovery of the fact to Gassendi. This rod had become magnetized by the continued action of the invisible power of which we speak. In later times it has been observed, that a bar of soft iron is, by the influence of the same power, converted into a temporary magnet, with a N. and S. pole, when it is placed in the direction which a magnetic needle assumes, and is inclined to the horizon.

If, in place of suspending the needle, or making it move horizontally on a pivot, we take an unmagnetized needle, and balance it upon a horizontal axis, then it will of course lie horizontally; but if we magnetize the needle, we shall find that it no longer remains horizontal, but takes an inclined position, or *dips*, as it is called; the *dip*, or the *inclination* downwards from a horizontal line, being about 70° in this country.

If we now take a magnetic needle, and suspend it by a silk fibre, we shall find that when it is pushed out of its position of rest, it will perform a certain number of oscillations in a given time before it again takes a fixed position. When this observation is made in different latitudes, it is found that the needle is brought to rest sooner in some places than in others; which proves that the intensity or strength of the magnetic force which directs the needle to the N. varies in different latitudes. Hence we have to consider three important classes of phenomena in reference to *terrestrial magnetism.*

1. The variation or declination of the needle, and its laws.
2. The dip or inclination of the needle.
3. The intensity of terrestrial magnetism; of which we shall treat as perspicuously and fully as the nature of the subject and our confined limits will permit.

SECT. I.—*On the Variation or Declination of the Needle.*

Variation of the needle.

A general account of the phenomena of the variation of the needle has been given in the order of their discovery in the historical part of this article. We shall now proceed to give a more minute account of them.

Measures of the variation of the needle have been taken by navigators and travellers in every part of the globe. Setting aside the inaccuracies common to them all, arising from the imperfect instruments which were in many cases employed, the observations made on shipboard were particularly liable to error, owing to the action which the iron on board exercised upon the compass.

Terrestrial Magnetism.

Halley.

The first person who attempted to collect and generalize the immense number of observations which had been made on the variation of the needle was Dr Halley, who published them in a sea-chart in 1700, in which he traced lines through all the parts of the globe where the variation was 0°, 5°, 10°, &c. These lines, which have since been called *Halleyan lines* or *curves*, excited great interest, and had the advantage of giving, at one glance, an ocular picture of the phenomena in every part of the world. As this *Variation Chart*, however, soon became old, from the rapid changes in the variation, as well as from confused methods of observation, Messrs Mountain and Dodson collected, from the records of the Admiralty, and from the papers of various naval officers, about 50,000, which they laid down in variation charts for 1745 and 1756.

Churchman.

The next step in the generalization of the phenomena of variation was made by Mr Churchman, who published in 1794 a programme of a *Magnetic Atlas.* He refers his variation lines to two poles, one of which he places, for the year 1800, in Lat. 58° N., and Long. 134° W. of Greenwich, very near Cape Fairweather; while the other pole is in Lat. 58° S., and Long. 165° E. of Greenwich. He supposes the northern pole to revolve in 1096 years, and the southern one in 2289 years.

Hansteen.

It is to Professor Hansteen, however, that we are indebted for the most satisfactory collection of observations on the variation of the needle, and for the most philosophical generalization of them. In the *Magnetic Atlas* which accompanies his work on the magnetism of the earth, he has published a variation chart for 1787, in which the irregularities and inflexions of the curves, and their total want of symmetry, prove how irregular are the causes on which terrestrial magnetism depends. In this chart the *western line of no variation*, or that which passes through all the places on the globe where the needle points to the true N., begins in Lat. 60°, to the W. of Hudson's Bay, proceeds in a S.E. direction through the North American lakes, passes the Antilles and Cape St Roque, till it reaches the South Atlantic Ocean, where it cuts the meridian of Greenwich in about 65° of S. Lat. This line of no variation is extremely regular, being almost straight till it bends round the eastern part of South America, a little S. of the equator. The *eastern line of no variation* is exceedingly irregular, being full of loops and inflexions of the most extraordinary kind, indicating the action of local magnetic forces. It begins in Lat. 60° S., below New Holland, crosses that island through its centre, extends through the Indian Archipelago with a double sinuosity, so as to cross the equator three times, first passing N. of it to the E. of Borneo, then returning to it and passing S. between Sumatra and Borneo, and then crossing it again beneath Ceylon, from which it passes to the E. through the Yellow Sea. It then stretches along the coast of China, making a semicircular sweep to the W., till it reaches the Lat. of 71°, where it descends again to the S., and returns northwards with a great semicircular bend, which terminates in the White Sea. These lines of no variation are accompanied through all their windings by other lines where the variation is 5°, 10°, 15°, &c.; these last lines becoming more irregular as they recede from those of no variation. In the South Pacific Ocean, and the equatorial part of the North Pacific, they are so little dependent on the lines of no variation, that they form returning curves of an elongated oval form, the curves of 2°, 3°, 4°, 5°, 6°, and 7°, crossing the equator and the tropic of Capricorn twice, so that, in the centre or axis of the ovals which these lines form, there should be a fragment of a line of no variation.

His variation chart.

Barlow.

The great changes which had taken place in the variation since 1787, and the number of new observations which had been made in every part of the world, induced Professor Barlow, in 1833, to construct a new variation chart.[1]

Four magnetic poles of Hansteen.

In the charts both of Hansteen and Barlow the variation lines exhibit a convergency at their extremities;[2] and Hansteen considers it proved that there are *four points of convergency*, two in each hemisphere, a weaker and a stronger, on opposite sides of the poles of revolution. These four points he considers as the *four magnetic poles* of the globe; and, by comparing observations which have been made at different times, he concludes that they have a regular motion round the globe, the two northern ones from W. to E., in an oblique direction, and the two southern ones from E to W., also obliquely. The following are the periods of their revolution, as calculated from the best observations previous to 1817, when his work was published:—

The *strongest* NORTH pole in 1740 years.
The *strongest* SOUTH pole in 4609 years.
The *weakest* NORTH pole in 860 years.
The *weakest* SOUTH pole in 1304 years.

Upon these data he computed the following table, showing the position of these poles from 1800 to 1850:—

Years.	Strongest North Pole.		Strongest South Pole.		Weakest North Pole.		Weakest South Pole.	
	West Longitude.	North Latitude.	East Longitude.	South Latitude.	East Longitude.	North Latitude.	West Longitude.	South Latitude.
1800	93° 33′	69° 53′	134° 8′	69° 7′	131° 43′	85° 25′	130° 28′	77° 50′
1810	91 28	69 45	133 21	68 59	135 54	85 18	133 14	78 3
1820	89 24	69 38	132 35	68 52	140 6	85 12	135 59	78 16
1830	87 19	69 30	131 47	68 44	144 17	85 6	137 45	78 29
1840	85 15	69 22	131 1	68 37	148 28	85 0	140 31	78 41
1850	83 10	69 14	130 14	68 29	152 40	85 0	143 16	78 54

Hansteen remarks, that the four periods above mentioned, viz., 860, 1304, 1740, and 4609, become, by a slight alteration, 864, 1246, 1728, and 4320; and he adds, rather fancifully for a matter of science, that these numbers are equal to 2 × 432, 3 × 432, 4 × 432, and 10 × 432, and that the number 432 is one of the most important among the sacred numbers of the Indians, Babylonians, Greeks, and Egyptians, which are said to depend on certain combinations of natural events. According to the mythology of the Brahmins, the duration of the world is divided into four periods; the first of which is 432,000 years; the second, 2 × 432,000; the third, and so in all $(1+2+3+4) = 10 \times 432{,}000$. Hansteen also considers it worthy of remark, that the sun's mean distance from the earth is 216 (the half of 432) radii of the sun, the moon's mean distance 216 radii of the moon, and, what he says is still more striking, $60 \times 432 = 25920$, the smallest number divisible at once by all the four periods; and hence, he adds, the shortest line in which all the four poles can accomplish a cycle, and return to the same state as at present, *coincides exactly with the period in which the precession of the equinoxes will amount to a complete circle*, reckoning the precession at a degree in 72 years.

Hansteen considers the four poles as originating in *two* magnetic axes, the two strongest being the termination of one axis, and the two weakest, of the other; and he conceives that they may have been produced either along with the earth itself, or at a later epoch. According to the first supposition, it is not easy to account for their change of position; but according to the last, they must have originated either from the earth alone, or from some external cause. If they originated in the earth, their change of position is still unsusceptible of explanation; and hence Hansteen conceives that they have their origin from the action of the sun heating and illuminating the earth, and producing a magnetic tension, as it produces electrical phenomena.

After the publication of Professor Hansteen's work, the valuable observations made during the British voyages of discovery in the arctic regions were given to the world; and by availing himself of these, and obtaining access to others unpublished in the marine chart office at the Admiralty, the Norwegian philosopher obtained more accurate determinations both of the positions and periods of revolution of the magnetic pole. The following is a brief abstract of his calculations:—

1. *Strongest North Pole.*—In 1813 the observations made on board H.M.S. Brazen, in Hudson's Bay, give 67° 10′ for the latitude of the strongest north magnetic pole, and 92° 24′ for its west longitude. Hence, by comparing this with previous determinations, we have—

	Latitude of Pole.	West Longitude of Pole.
1730	70° 45′	108° 6′
1769	70 17	100 2
1813	67 10	92 24

From these data we obtain the motion of the pole to the E.

Epochs.	Years.	Change of Place in Longitude.	Annual Motion.
From 1730 to 1769	39	8° 4′	12′ 44″
1769 to 1813	44	7 38	10 41

From which we obtain—

Mean annual motion of the pole	11′ 4″·25
Period of complete revolution	1890 years.

In August 1819, Captain Parry was to the N. of this pole, and found the dip to be 88° 37′, and on the 11th September he was three degrees W. of the pole. Hence, as his latitude was then 74° 27′, the latitude of the pole must have been about 71° 27′.

According to the more recent observations of Commander Ross, this pole, upon which he erected a flag, is situate in north latitude 70° 5′ 17″, and west longitude 96° 45′ 48″, which coincides strikingly with Hansteen's result. According to the survey of Lieut.-Col. Lefroy in 1843 and 1844, this pole was situate in north latitude 52° 19′, and west longitude 92°. Its force was 1·88 in the arbitrary, and 14·2 in the absolute scale. Hence the attractive forces at the strongest and weakest north poles are as 14·2 to 13·3, or nearly as 107 to 100.

2. *Strongest South Pole.*—By combining the observations of Cook in 1773 and 1777, with those of Furneaux in 1773, and comparing these with Tasman's observations in 1642, Hansteen has found the following position of it:—

---

[1] See *Philosophical Transactions*, 1833, pp. 667-675, and plates xvii. and xviii.

[2] Professor Barlow remarks that the very spot where Sir James Ross found the needle perpendicular, "that is, the pole itself, is precisely that point in my globe and chart in which, by supposing all the lines to meet, the several curves would best preserve their unity of character, both separately and conjointly, as a system."

	Motion in 131 Years.
1642, N. Lat. 71° 5′; E. Long. 146° 57′.........	10° 14′
1773, N. Lat. 69° 26′ 5″; E. Long. 136° 15′ 4″	

Hence the real motion of this pole in 131 years is 10° 14′ or 4′·67 annually, and its period of complete revolution will be 4605 years.

3. *Weakest North Pole.*—By comparing observations made in 1770 and 1805, at Tobolsk, Tara, and Udinsk, in Siberia, Professor Hansteen found—

	North Latitude.	East Longitude.	Motion in 35 Years.	Annual Motion.
1770	85° 46′	91° 29′ 30″	14° 35′	35′·128
1805	85 21½	116 19		

Hence this pole completes its revolution from E. to W. in 860 years. By the observations of Hansteen in 1828–9 this pole is in east longitude 120°, its force in the arbitrary scale 1·76, and in the absolute scale 13·3.

4. *Weakest South Pole.*—By comparing observations made by Cook and Furneaux in 1774, with those recorded by Halley as made in 1670, Hansteen obtained the followin results:—

	South Latitude.	West Longitude.	Motion in 104 Years.	Annual Motion.
1670	64° 7′	94° 33½′	28° 43½′	16′·57
1774	77 17	123 17		

Hence this pole completes its revolution from E. to W. in 1303 years.

The Rev. Mr Grover has recently endeavoured to show "that the movement of the magnetic pole governing Europe is capable of recognition, and that it possesses an orbitual character, the general features of which can be distinctly traced." The form of the magnetic orbit which he has deduced from a careful examination of authentic observations made at London, Paris, and St Petersburg, is shown in the annexed figure, where N is the true north pole, in the middle of a section of the northern hemisphere, and the irregular elliptical curve the path of the pole, so far as hitherto observed. The place of the pole at different times between 1580 and 1846 are marked on the curve. The isodynamic poles, or those to which the lines of equal magnetic intensity converge, as shown in fig. 62, are marked by the letters A and S. In the course of his investigation, Mr Grover has noticed a certain acceleration and retardation of the motion, and the opposite bias of the two isodynamic hemispheres, and deduces some curious facts explanatory of the ovals, loops, and singular curvatures of the magnetic lines. Mr Grover regards the ovals as produced temporarily from the peculiar position of the moving magnetic pole in relation to the isodynamic poles A and S, by which a bias is given to the needles of a whole district.

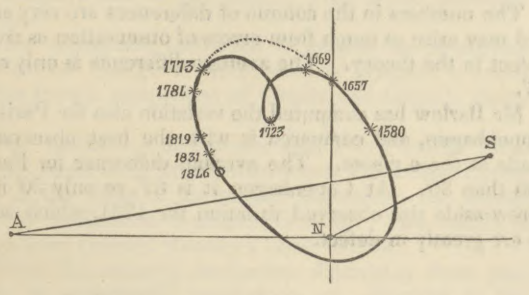

Fig. 57.

Professor Barlow endeavoured to deduce the position of the magnetic pole, upon the supposition that the magnetic phenomena of the earth are analogous to those exhibited by a simple iron ball. The tangent of the dip being equal to double the tangent of the magnetic latitude, Mr Barlow supposes π to be the magnetic pole, N, S the terrestrial poles, and L a known place where the dip and variation have been well ascertained. Then by the dip we obtain the magnetic latitude πL; NL being the terrestrial latitude, and $NL\pi$ the variation. Hence, in the spherical triangle $NL\pi$, we have two sides and the contained angle to find the side $N\pi$ the terrestrial latitude of the magnetic poles, and πNL the longitude of the same pole, in reference to the meridian NL.

In making this computation, Mr Barlow selected a certain number of the best observations on the dip and variation of the needle, made in different parts of the world, and he obtained the following results :—

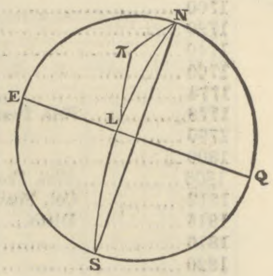

Fig. 58.

Place of Observation.	Date.	Dip.	Variation.	Computed Place of Magnetic Pole. N. Lat.	Computed Place of Magnetic Pole. W. Long.
Tristan d'Acunha..	1821	37°53′ S.	12° 0′ W.	70° 56′	49° 33′
Trinidad	1821	10 27 N.	5 0 W.	73 59	47 20
St Jago	1820	48 0 N.	15 55 W.	69 37	67 4
Teneriffe	1820	58 22 N.	20 47 W.	69 49	69 14
Madeira	1820	63 47 N.	23 7 W.	68 4	65 26
Madrid	1799	67 41 N.	19 59 W.	72 47	50 33
Paris	1814	68 36 N.	22 34 W.	75 31	67 4
London	1818	70 34 N.	24 30 W.	75 2	67 41
Berlin	1805	69 53 N.	18 2 W.	79 2	70 44
Copenhagen	1813	71 26 N.	18 22 W.	79 43	67 38
Davis' Straits	1820	83 43 N.	60 20 W.	67 37	94 26
Regent's Inlet	1820	88 26 N.	118 16 W.	71 10	98 16
Baffin's Bay	1820	84 30 N.	82 2 W.	71 13	97 3
Possession Bay......	1820	86 4 N.	108 46 W.	69 40	99 10
Melville Island......	1820	88 43 N.	127 46 E.	73 12	.102 46

Among these results there is a discrepancy of no less than 55° in longitude, and 10° in latitude; and hence Mr Barlow concluded that every place has its particular polarizing axis, which probably in all cases falls within the frigid zones, varying within these limits through all possible degrees of latitude and longitude.

These aberrations Mr Barlow ascribed to local inequalities in the distribution of the ferruginous parts of the terrestrial sphere.

In the last edition of this work we published extensive tables of the variation from observations collected by Hansteen, and communicated to us by himself. Although these tables must always be valuable, as containing important facts in terrestrial magnetism, yet so many new measures have been taken of the variation of the needle in all parts of the world, that a complete table of the latest results would be quite unsuited to a work like this.

General Sabine recently collected all the best observations, and published them graphically in his interesting *Map of the Lines of Equal Declination for the Epoch of* 1840.

On the progressive Changes in the Variation of the Needle.

Change in the variation.

We have already seen that the variation of the needle experiences a progressive change in every part of the globe. The following table shows very satisfactorily the change which has taken place in London :—

Table of the Variation at London from 1576 to 1831.

Years.	Observers.	Variations.	
1576................	Norman................	11° 15′	easterly.
1580................	Burroughs............	11 17	maximum.
1622................	Gunter	6 12	...
1634................	Gellibrand............	4 5	...
1657 1662	....	0 0	no variation.

Years.	Observers.	Variations.	
1666		0 34	westerly.
1670		2 6	...
1672		2 30	...
1700		9 40	...
1720		13 0	...
1740		16 10	...
1760		19 30	...
1774		22° 20′	
1778	*Phil. Trans.*	22 11	...
1790		23 39	...
1800		24 36	...
1806	*Phil. Trans.*	24 8	...
1813	Col. Beaufoy	24 20 17″	...
1815	Ditto	24 27 18	maximum.
1816		24 17 9	...
1820		24 11 7	...
1823		24 9 40	...
1831		24 0 0	...

The following table shows the progressive change in the variation of the needle at Paris:—

Table of the Variation at Paris from 1541 *to* 1829.

Years.	Variations.	Years.	Variations.
1541	7° 0′ easterly.	1683	3° 50′ westerly.
1550	8 0 ...	1700	7 40 ...
1580	11 30 maximum.	1750	17 15 ...
1603	8 45 ...	1767	19 16 ...
1618	8 0 ...	1780	20 35 ...
1630	4 30 ...	1785	22 0 ...
1640	3 0 ...	1800	22 12 ...
1659	2 0 ...	1807	22 34 ...
1664	0 40 ...	1814	22 54 ...
1669	0 0 no variation.	1819	22 29 ...
1667	0 15 westerly.	1824	22 23 ...
1670	1 30 ...	1829	22 12·5 Arago.
1680	2 40		

The following table shows the progressive change in the variation in the southern hemisphere since the time of Vasco de Gama:—

Table of the Variation at the Cape of Good Hope.

Years.	Variations.	Years.	Variations.
1605	0° 30′ easterly.	1724	16° 27′ westerly.
1609	0 12 westerly.	1752	19 0 ...
1614	1 30 ...	1768	19 30 ...
1667	7 15 ...	1775	21 14 ...
1675	8 30 ...	1791	25 40 maximum.
1702	12 50 ...	1804	25 4 ...

Professor Hansteen has explained these progressive changes in the variation of the needle by the motion of the four magnetic poles. Taking the variations at Paris for the northern hemisphere, he remarks that in 1580 the weak N. pole in Siberia was about 40° E. of Greenwich, or to the N. of the White Sea; while the strong American pole was about 136° W. of Greenwich, or 36° E. of Behring's Straits. The W. pole, therefore, lay *nearer* Europe than now, and the strong one *more remote*. Hence the action of the former predominated, and drew the needle eastward. But the *weak* pole now withdrew itself towards the Siberian Ocean, from Europe, and the *strong one* approached it. The action of the latter therefore predominated, and the needle turned westward till 1814, in which year it reached its greatest declination, and commenced its easterly course.

The explanation is equally satisfactory in reference to the southern hemisphere, and the variation at the Cape. In 1605 the *weak* S. pole was 76½° W. of Greenwich, and the *strong* S. pole about 150° E. of that meridian. The weak pole was, therefore, much *nearer* the Cape than now, while the stronger pole was *more remote* from it. The influence of the *weak* pole was therefore most powerful, so that the S. pole of the needle moved towards the W., and its N. pole more towards the E. But when the *weak* S. pole receded from the Cape, and the *strong* one approached it, the S. pole of the needle turned more and more towards the strong pole, and its declination became consequently more westerly.

Mr Barlow has therefore given the following rule for calculating the variation of the needle, on the supposition that the magnetic pole which governs the needle in London was in 1818 in N. Lat. 75° 2′, and W. Long. 67° 41′, and that its motion was uniform at the rate of 4° 14′ in *ten* years, the variation being 0°, or the pole being in the meridian of London, in 1660.

Rule.—To the co-tangent of half the angle πNL (see the last figure), add the constant log. 1·65642; find the angle of which the sum is the tangent, and call it arc (A). To the same co-tangent add the log. 0·03987, and find the arc of which the sum is the tangent, and call it arc (B).

Then B − A will be the variation or the angle πLN. The following comparison of the variations thus computed with actual observation is very interesting:—

Years.	Variations.		Differences.	Observers.
	Observed.	Computed.		
1660	0° 0′	0° 0′	0° 0′	Bond.
1670	2 30	2 44	0 14 +	Halley.
1690	6 0	7 59	1 59 +	Ditto.
1720	14 17	14 47	0 30 +	Graham.
1740	17 0	18 20	1 20 +	Ditto.
1750	17 48	19 47	1 59 +	Ditto.
1770	21 9	22 4	0 55 +	Heberden.
1780	23 17	22 54	0 23 −	Gilpin.
1790	23 39	23 33	0 6 −	Ditto.
1800	24 3	24 1	0 2 −	Ditto.
1810	24 11	24 18	0 7 +	Ditto.
1818	24 30	24 30	0 0	...

The numbers in the column of differences are very small, and may arise as much from errors of observation as from a defect in the theory. The average difference is only about 45′.

Mr Barlow has computed the variation also for Paris and Copenhagen, and compared it with the best observations made at these places. The average difference for Paris is less than 30′. At Copenhagen it is 37′, or only 20′ if we throw aside the observed variation for 1731, which seems to err greatly in defect.

On the Annual Variation of the Needle.

Annual variation. Cassini.

Besides the progressive changes in the declination of the needle, M. Cassini observed an *annual* change, depending on the position of the sun in reference to the equinoctial and solstitial points.

Between the months of *January* and *April* the magnetic needle recedes from the N. pole of the globe, so that its western declination increases.

From *April* to the beginning of *July*, that is, from the vernal equinox to the summer solstice, the declination diminishes, or the needle approaches the N. pole of the globe.

From the summer solstice to the vernal equinox, the needle, receding from the N. pole, returns to the W., so that in October it has nearly the same position as in May, and between October and March the western motion is smaller than in the three preceding months.

Hence it follows, that during the *three* months between the vernal equinox and the summer solstice, the needle retrogrades towards the E.; and during the following *nine* months its general motion is towards the W.

Arago.

This important subject particularly occupied the attention of M. Arago. Taking the mean declination of each day, or that of the maximum and minimum, and the mean declination of each month, he arranged in tables the mean monthly declinations at Paris from 1784 to 1788, and also those at London, near the equinoxes and solstices, from 1793 to 1805, as calculated from the observations of Mr Gilpin, and, by a comparison of the results, he found a maximum of declination towards the vernal equinox, and a minimum towards the summer solstice; but this difference was less at London than at Paris.

In comparing the observations of Cassini in 1786 with those of 1800, corresponding to the measures of Gilpin, M. Arago found that they do not differ from one another in their magnetical relations, but in one point. In 1786 the annual change of declination was nine minutes, whereas in 1800 it was scarcely a minute. Hence he observed, that the retrograde motion which the needle experiences between the vernal equinox and the summer solstice decreases at the same time with the general and annual motion towards the W.

At Salem, in Massachusetts, where observations were made in 1810 by M. Bowditch, the declination is W., and has diminished for a great number of years about 2 minutes annually. In examining these observations, M. Arago did not find any trace of the period of Cassini. The declination has never diminished between the vernal equinox and the summer solstice, but it gradually increases from April to August. This increase is compensated by a decrease of the declination between September and December, so that the period seems to be transferred from spring to autumn. M. Arago conceived that if this idea should be found correct, the annual changes would be regulated by the following principles:—

1. When the needle, having a westerly declination, recedes from the meridian, it experiences a retrograde motion, which brings it back to this place. This is the discovery of Cassini.

2. This retrograde oscillation is greater in proportion as the annual change of declination is greater; a result deducible from a comparison of Cassini and Gilpin's observations.

3. The oscillation disappears, and every month gives nearly the same mean declination, when, the needle having arrived at the limit of its western digression, the annual change of declination becomes nothing. This result is deduced from Colonel Beaufoy's observations.

4. When the westerly declination diminishes from year to year, no remarkable oscillations are observed in the needle towards the E., excepting between the months of September and December. This is the observation of Mr Bowditch. According to Colonel Beaufoy's observations, the daily variation is greatest in *June* and *August*, and less in July, so that the annual curve has two *maxima* and two *minima* in the course of the year, the two maxima being in June and August, and the two minima in December and July.

On the Diurnal Variations of the Needle.

Diurnal variation.

That there is a daily change in the variation of the needle, as originally discovered by Mr Graham in 1724, has been placed beyond a doubt by observations made with the most accurate instruments in almost every part of the world. The following table contains the mean diurnal changes in the variation, according to the observations of Canton in 1759, of Gilpin in 1787 and 1793, and of Colonel Beaufoy in 1817-19.

Table of the Mean Daily Changes in Variation.

Months.	Observations of Canton. 1759.	Observations of Gilpin.		Colonel Beaufoy.
		1787.	1793.	1817-18-19.
January	7′ 8″	10′ 2″	4′ 3″	5′ 3″
February	8 58	10 4	4 6	6 3
March	11 17	15 0	8 5	8 22
April	12 26	17 4	11 7	11 48
May	13 0	18 9	10 4	9 53
June	13 21	19 6	12 6	11 15
July	13 14	19 6	12 5	10 43
August	12 19	19 4	12 1	11 26
September	11 43	15 5	9 8	9 44
October	10 36	14 3	7 0	8 46
November	8 9	11 1	3 8	7 10
December	6 58	8 3	3 8	4 7
Mean daily change	10 43	14 39	8 0	9 32

The following ranges in the variation for every month were obtained by Dr Lloyd from the Dublin observations during the years 1840–43.

Summer Half-Year.			Winter Half-Year.		
Month.	Westerly movement.	Easterly movement.	Month.	Westerly movement.	Easterly movement.
	Min.	Min.		Min.	Min.
April	13·3	11·6	October	7·8	9·7
May	12·2	8·4	November	4·8	7·0
June	12·3	9·2	December	3·9	6·6
July	11·6	9·2	January	5·2	7·6
August	11·8	10·2	February	6·8	8·1
September	10·1	10·8	March	9·7	10·5
Mean	11·9	9·9	Mean	6·4	8·3

It is remarkable, as noticed by Dr Lloyd, that the mean ranges of the easterly movements for the entire year are precisely equal, the mean value of each being 9′·1

Dr Lloyd has shown, from the Dublin observations, that the curves representing the annual variations in the declination of the needle, and in the temperature of the air, present the most complete accordance, not only as to the hours of *maxima* and *minima*, but in their entire course. Mr Horner obtained the same result from the Stockholm observations.[1]

Dr Lloyd has obtained the following measures of the secular variation:—

Year.	Variation.	Difference.
	Deg. Min.	Min.
1840	332 30·69	...
1841	332 34·65	+31·96
1842	332 43·55	+ 8·90
1843	332 50·10	+ 6·55
1844	332 53·43	+ 3·33
1845	332 59·75	+ 6·32
1846	333 7·22	+ 7·47

The variation is here measured from the N. *eastward.*

From these results Dr Lloyd concludes that the N. end of the magnet moves to the *east* from year to year, and that the westerly variation diminishes by 6′·06 annually in its mean quantity.

---

[1] *Transactions of the Royal Irish Academy*, vol. xxii., part 1, 1849.

The following Table shows the Amount of the Daily Variation at other places compared with that at London.

London, general mean	60′	44″	
Geneva	15	42	Saussure.
Chamouni	17	6	
Col du Geant	15	43	
Freiberg	12	11·9	
Petersburg	12	10·1	
Nicolaeff	10	53·4	
Kasan	70	36·5	

When the diurnal variation of the needle was first discovered, it was supposed to have only two changes in its movements during the day. About seven A.M. its N. end began to deviate to the W., and about two P.M. it reached its maximum westerly deviation. It then returned to the eastward to its first position, and remained stationary till it again resumed its westerly course in the following morning. When magnetic observations became more accurate, it was found that the diurnal movement commences much earlier than seven A.M., but its motion is to the E. At half-past seven A.M. it reaches its greatest easterly deviation, and then begins its movement to the W. till two P.M. It then returns to the eastward till the evening, when it has again a slight westerly motion; and in the course of the night, or early in the morning, it reaches the point from which it set out twenty-four hours before. The most accurate observations made in England were those of Colonel Beaufoy, when the variation was about 24½′ W. In these the absolute maxima were earlier than in Canton's observations, and the second maxima W. about eleven P.M.

The following were the diurnal changes observed at Paris:—During the night it is nearly stationary. At sunrise its north extremity moves to the westward, as if it were avoiding the solar influence. Towards noon, or more generally from noon to three o'clock, it attains its maximum westerly deviation, and then it returns eastward till nine, ten, or eleven o'clock in the evening; and then having reached its original position, it remains stationary during the night. The amount of this daily variation is, for April, May, June, July, August, and September, from 13′ to 15′; and for the other six months of the year, from 8′ to 10′. On some days it rises to 25′, and on others it does not exceed 5′ or 6′.

According to M. Dove, the maximum easterly deviation of the needle takes place at eight A.M. at Freiberg, Nicolaeff, and St Petersburg, and at nine A.M. at Kasan; and the maximum of westerly deviation at two P.M. at Kassan, Nicolaeff, and St Petersburg, and at one P.M. at Freiberg.

In the northern regions, such as Denmark, Iceland, and Greenland, the diurnal variations are greater, and less regular. The needle is not stationary during the night, and it does not reach its maximum westerly deviation till between eight and ten P.M., and its most easterly about nine or ten A.M.

In advancing from the N. to the magnetic equator, the diurnal variation diminishes in amplitude, and it ceases to be perceptible in the magnetic equator. Captain Duperrey, however, found that when the place is either under the magnetic equator, or at a little distance from it, the N. point of the needle advances every morning to the *west* or to the *east*, according as the sun passes to the *north* or to the *south* of the place of observation.

In the southern magnetic hemisphere the daily variation takes place in an opposite manner, the *north* end of the needle moving to the E. at the same hours that it did to the W. in the northern hemisphere; a result which was established by the observations of Mr J. Macdonald at St Helena, and at Fort Marlborough, in Sumatra.[1] M. Freycinet was led to the same result by observations made in the Isle of France, Timor, Rawak, Guham, Mowi, Port Jackson, and other places. At the Marianne and Sandwich Isles, in the northern hemisphere, the *north* point of the needle moves to the W., as in Europe, from eight A.M. till one P.M., though the variation there is easterly. At Timor, Rawak, and Port Jackson, to the S. of the equator, the N. point of the needle moves during the morning in an opposite direction; hence the observations made to the N. of the line agree with those in Europe, while those in the southern hemisphere, like those of Macdonald, exhibit an opposite motion. M. Freycinet found that the diurnal oscillations have a small amplitude between the tropics. At Rawak, only the fortieth of a degree S. of the equinoctial line, M. Freycinet found that the needle oscillated every day with an amplitude of 3′; so that it is the magnetic, and not the terrestrial, equator, as Duperrey afterwards found, which separates the zone of westerly from the zone of easterly diurnal variations.

Observations are still wanting to show whether or not the daily variations have the same direction in places where the variation is westerly and in those where it is easterly.

The dipping needle also undergoes, as will be afterwards seen, daily variations, but their amplitude is of less amount. There can be no doubt, as M. Pouillet observes, that a needle capable of moving in any given azimuth will experience daily changes; and that a needle moveable in every direction round its centre of gravity would describe every day a cone whose base would be an ellipse, or some other curve more or less elongated, in different parts of the earth.

Cause of the diurnal variation.

The sun is now universally allowed to be the cause of the diurnal variations of the needle. Canton ascribed them to the action of solar heat, having ascertained that heat tends to diminish the attractive powers of a magnet, and assuming that the direction of the needle was due to the resultant of all the magnetic forces of the terrestrial sphere. When the sun was to the eastward of the needle, the forces lying to the eastward suffered a diminution of power, in consequence of which the westerly force prevailed, and the N. end deviated to the W. When the sun, on the other hand, was to the westward of the needle, the power on that side diminished, and the needle returned again to the eastward. Canton, however, did not give any explanation of the morning easterly variation of the needle.

On the Irregular Motions of the Magnetic Needle as produced chiefly by the Aurora Borealis.

Irregular motions of the needle produced by the aurora borealis.

Besides the regular changes of an annual and diurnal nature to which the needle is subject, it is sometimes affected with sudden and extraordinary movements, to which Baron Humboldt has given the name of *magnetic storms* or *hurricanes*, during which the needle traverses with a shivering motion, and often oscillates several degrees on each side of its mean position.

These sudden and capricious motions have been most frequently observed during the existence of the *auroræ boreales*, and have therefore been ascribed to that cause. The influence of this meteor on the magnetic needle was first noticed by Wargentin in 1750. It was observed by Bergman and others; and Van Swinden remarks, that he seldom failed to observe auroræ boreales after any anomalous motion of the needle; and he always concluded that there must have been one at the time, though he did not see it. As needles made of other substances, such as copper or wood, have not been found to be affected, the action of the aurora cannot be considered as an electrical one.

The influence of the aurora on the needle was particu-

---

[1] Made in 1794, 1795, and 1796; see *Philosophical Transactions.* Mr Macdonald observes, that the diurnal variations are sensibly less between the tropics than in Europe.

Terrestrial Magnetism.

Dr Dalton's observations.

larly studied by Dr Dalton, who has stated his views in his *Meteorological Observations and Essays*, published in 1793, in a dissertation of great ability, which has never received the notice which it merits. He has shown that the luminous beams of the aurora are parallel to the dipping needle; that the rainbow-like arches cross the magnetic meridian at right angles; that the broad arch of the horizontal light is bisected by the magnetic meridian; that the boundary of a limited aurora is half the circumference of a great circle crossing the magnetic meridian at right angles, the beams perpendicular to the horizon being only those on the magnetic meridian.

Dr Dalton has shown, from numerous observations, that the aurora exercises an irregular action on the magnetic needle; and he has deduced from these observations the following results:—

1. When the aurora appears to rise only about 5°, 10°, or 15°, above the horizon, the disturbance of the needle is very little, and often insensible.

2. When it rises up to the zenith, and passes it, there never fails to be a considerable disturbance.

3. This disturbance consists in an irregular oscillation of the horizontal needle, sometimes to the eastward and then to the westward of the mean daily position, in such sort that the greatest excursions on each side are nearly equal, and amount to about half a degree each at Kendal.

4. When the aurora ceases, or soon after, the needle returns to its former station.

Professor Hansteen's observations on the magnetical influence of the aurora are peculiarly interesting. He states that the extraordinary shivering movements of the needle are perhaps never exhibited except when the aurora is visible; and that this disturbance seems to operate at the same time in places the most widely separated. The extent of these movements may in less than twenty-four hours amount to five or five and a half degrees. In such cases, he adds, the disturbance is also communicated to the dipping needle; *and as soon as the crown of the aurora quits the usual place* (*the points where the dipping needle produced would meet the sky*), *that instrument moves several degrees forward*, and seems to follow it. After such disorders, he continues, the mean variation of the needle is wont to change, and not to recover its previous magnitude till after a new and similar disturbance. During the continuance of the aurora borealis, the intensity of the earth's magnetic force seems to grow weaker; for which reason the needle recedes from that magnetic pole where the ray of the aurora is displayed.

The influence of the aurora borealis on the needle was studied with particular care by M. Arago, whose accurate and regularly continued series of observations on the daily changes of the magnetic needle at Paris enabled him to compare these changes with the occurrence of the northern light. The following is an abstract of his views on the subject:—The appearance of an aurora causes the magnetic needle to vary several degrees to the E. and W. of its mean position. In the region where it appears, luminous beams, differently coloured, shoot up from all points of the horizon; *and the part of the heavens where all these beams or radiations unite is precisely that to which a magnetic needle directs itself when suspended by its centre of gravity.* M. Arago also showed that the concentric circles, which become visible almost always before the luminous beams, rest each upon the two points of the horizon equally distant from the magnetic meridian, *and that the most elevated points of each arch are exactly in this meridian.* From these two facts, he concludes that there is a relation between the causes of the aurora borealis and the motions of the magnetic needle; and, from observations made in places remote from each other, he infers that the aurora acts even before it shows itself in the horizon, and that its influence is exerted at very considerable distances. In a subsequent paper on the subject, M. Arago showed that the auroræ which are visible only in America, at St Petersburg, and in Siberia, in spite of the immense distance which separates us from these regions, produces a perceptible derangement of the magnetic needle at Paris. M. Arago at first believed that even the auroræ of the southern hemisphere extended their influence to Paris; but he afterwards found, that on the days when these southern auroræ took place, the phenomenon was observed also in the N., so that no conclusion can be properly deduced from this coincidence with the observed derangements of the needle.

Kupffer.

M. Kupffer confirmed by his own observations the first results obtained by M. Arago, and concluded that the aurora extends its influence to a great distance. When the needle was driven from its mean position by the influence of this meteor, M. Kupffer could not perceive any sensible difference between the duration of an oscillation at this time and at any other. He has, however, excepted some cases where the deviation was very considerable; but what was very remarkable was, that when the needle deviated to the E., the duration of an oscillation was greater than usual, whilst on the 24th November 1825, when the needle deviated to the W., the duration of an oscillation was smaller. On the other hand, the dip being in the ratio of the duration of the oscillation, the preceding observations seem to prove that the dip diminishes when the needle deviates to the W., and increases with an easterly deviation.

Notwithstanding the body of evidence which proves the connection between the aurora and the derangement of the needle, it is a very remarkable fact, that during the frequent occurrence of that meteor at Port Bowen, Captain Foster did not observe any peculiar changes in the deviation of the needle, although, from his vicinity to the magnetic pole, the diurnal variation sometimes amounted to 4° or 5°, and it was to be presumed that the slightest action of the aurora would, under such circumstances, have been visible. From these observations of Captain Foster and others, the natural conclusion is, that there are some auroræ which do not disturb, while there are others which do disturb, the magnetic needle.

During Captain (now Sir George) Back's residence at Fort Reliance (N. Lat. 62. 46. 29., and W. Long. 109. 0. 39.) for *six* months in 1833–4, and *four* months in 1834–5, the aurora occurred almost every night. The magnetic needle seems to have been constantly affected by it, and on one occasion the effect exceeded *eight degrees.* "Brilliant and active coruscations of the aurora borealis," says Sir G. Back, "when seen through a hazy atmosphere, and exhibiting the prismatic colours, almost invariably affected the needle. On the contrary, a very bright aurora, though attended by motion, and even tinged with a dullish red and a yellow, in a clear blue sky, seldom produced any sensible change, beyond, at the most, a tremulous motion.

"A dense haze or fog, in conjunction with an active aurora, seemed uniformly favourable to the disturbance of the needle; and a low temperature was favourable to brilliant and active coruscations. On no occasion, during two winters, was any sound heard to accompany the motions. The aurora was frequently seen at twilight, and as often to the eastward as to the westward. Clouds, also, were often perceived in the day time, in form and disposition very much resembling the aurora."

Christie.

Mr Christie explained the absence of any apparent action of the aurora, by the supposition that the apparatus employed was not fitted to exhibit that action; and he entertained therefore the opinion, "that changes in the deviation and intensity of the terrestrial forces are simultaneous with the aurora borealis." The following is the method

Christie.

recommended by Mr Christie for observing the effects of the aurora to the greatest advantage :—

"If the magnetic forces brought into action during an aurora are in the direction of the magnetic meridian, they will affect a dipping needle adjusted to the plane of that meridian ; but the direction of a horizontal needle will remain unchanged. On the other hand, if the resultant of these forces makes an angle with the meridian, the direction of the horizontal needle will be changed, but the dipping needle may not be affected. In order to determine correctly the negative influence of the aurora, by means of a horizontal needle, it is therefore necessary not only to have regard to those forces which influence its direction, but likewise to those which affect the horizontal intensity. . The effects of the former are the objects of direct observation, but those of the latter are not so immediately observable. As, during an aurora, the intensity may vary at every instant, and it is these changes which are to be detected, the method of determining the intensity by the time of vibration of the needle cannot here be applied, and other means must be adopted. The best method appears to me to be that which I employed for determining the diurnal variation of the horizontal intensity, the needle being retained nearly at right angles to the meridian by the repulsive force of a magnet, or by the torsion of a fine wire or thread of glass. For the purpose, then, *of detecting, in all cases, the magnetic influence of the aurora*, I consider that two horizontal needles should be employed ; one adjusted in the meridian, for determining the changes which may take place in the direction of the horizontal force, and the other at right angles to the meridian, to determine the changes in the intensity of that force, arising principally from new forces in the plane of the meridian, and which would affect the direction of the dipping needle alone. Both these needles should be delicately suspended, either by very fine wire, or by entwisted fibres of silk. In order to render the changes in the direction of the needle in the meridian more sensible, its directive force should be diminished by means of two magnets N. and S. of it, and having their axes in the meridian. These magnets should be made to approach the needle until it points about 30° on either side of the meridian, and they should be so adjusted that the forces acting upon the needle will retain it *in equilibrio*, with its marked end at about 30° to the E. and 30° to the W. of N., and also at S. The needle is to be left with its marked end pointing S., for the purpose of observing the changes occurring in its direction. If magnets are employed to retain the second needle nearly at right angles to the meridian, they should be made to approach its centre until the points of equilibrium are at about 80° E., 80° W. and S., the observations being made with the needle at 80° E. and 80° W. An objection to this method of adjusting this needle by means of magnets is, that any change in their temperature will have a very sensible effect on the direction of the needle in this position ; and should such change take place during the observations, corrections must be applied to the results before any accurate conclusions can be drawn from them. I have before remarked, that this inconvenience will be in a great measure obviated by employing the torsion of a fine wire, or a very fine plummet of glass, to retain the needle at about 80° from the meridian. In this case, the ratio of the force of torsion to the terrestrial force acting upon the needle having been determined, a measure will be obtained of the changes which take place in the intensity of the terrestrial force during the occurrence of an aurora. It is very desirable that it should be ascertained whether the effects on the needle are simultaneous with any particular class of phenomena connected with the aurora ; whether these effects are dependent on the production of beams or coruscations, or on the formation of luminous arches ; or whether any difference exists in the effects produced by them. In order to determine this, it is necessary that the times of the occurrence of the different phenomena, and also of the changes in the directions of the needles, should be accurately noted ; and for such observations three observers appear to be indispensable."

Influence of electricity on the needle.

Mr Christie.

Sir Everard Home.

It has been considered a question of some importance, whether the electric state of the clouds produces any effects upon the needle : and this question has increased in interest since the discovery of the magnetical effects of galvanic and common electricity. Mr Christie made some valuable observations on this subject. Adjusting in a particular manner a needle between two magnets, so that its directive force was considerably diminished, he found that changes in the position of electric clouds were accompanied by changes in the position of the needle. Captain Sir Everard Home also observed, that, in two instances, a vibrating needle came sooner to rest during a thunder-storm than it did either before or after it. The number of vibrations was reduced in one case from 100 to 40, and in another from 200 to 120.

Sir George Back.

An analogous fact was observed by Sir George Back, in 1833, at Fort Alexander, at the southern extremity of Lake Winnipeg, where a "considerable alteration appeared, both in the number of vibrations, and the point at which the needle finally rested. A second time showed a similar discrepancy. The reason of this peculiarity I could not divine, until about an hour afterwards, when some gentlemen arrived from the westward, and acquainted us that they had just encountered a severe thunder-shower, though the sky over the fort underwent no visible change, and wore the same sultry aspect as it had done most of the forenoon."[1]

The view which we have given, in a subsequent section, of the magnetic condition of our atmosphere, arising from the uniform dissemination of ferruginous and other metallic matter, enables us to give a satisfactory explanation of the general phenomena of the aurora, of its action on the needle, and of the circumstances under which it will affect or not affect its stability. That there is magnetic matter in the atmosphere is indubitable, and that this matter may be heated by the electricity of the atmosphere, so as to give out light of different colours, and may have its magnetic influence increased or diminished by this electrical action, as well as by ordinary changes of temperature, cannot be doubted. When the magnetic forces are in a state of equilibrium, the needle will take its mean position, subject only to those diurnal changes which arise from the action of solar heat. But when the magnetic matter is exposed to the electrical agents which exercise so powerful an influence on the regions of the clouds, when the ferruginous matter, and the other metallic vapours which accompany it, are rendered luminous by the transmission of the electric fluid, and when the magnetic matter has its induced magnetism either diminished or increased by this cause, the resultant of the forces which act upon the needle must be changed, and motions regular and irregular, easterly and westerly, or in any given direction, communicated to a needle freely suspended by its centre of gravity. A local displacement of the magnetic matter, by the various causes which are constantly disturbing our atmosphere, or local and limited electric action, must necessarily affect such a needle ; but it is easy to conceive that those local and limited actions may be such as to balance each other, and not change the direction of the resultant force which acts either upon a horizontal or a dipping needle. Nay, it is easy to conceive a general diffusion of electricity, capable of illuminating the magnetic matter with such perfect equality in all magnetic azimuths, without at all affecting any needle, however balanced or suspended; because the electrical influence may not change the direction of the resulting forces which give the needle its mean direction. In such a case, however, it is probable that the magnetic intensity might be increased or diminished during the existence of such an electric state of the magnetic matter. We cannot, therefore, adopt the opinion of Mr Christie, *that every aurora must disturb the magnetic needle;* and we admit only the observed fact, that there are auroræ which disturb, and auroræ which do not disturb the needle.

---

[1] *Narrative of the Arctic Land Expedition*, &c., p. 41, 42.

In order to explain more fully our views on this subject, let us suppose our magnetic atmosphere to be undisturbed by any cause, and that the needle in every magnetic meridian rests in a state of perfect equilibrium in its mean position. Let us now suppose that the magnetic atmosphere is disturbed in east longitude 90° and latitude 0°, either by a change of temperature, or by electric action, or by any cause which displaces the magnetic matter from that meridian, or accumulates it there. Such a change must necessarily affect the horizontal magnetic needle in all places to the east and west of it; but it will not affect the horizontal needle in the meridian where it takes place, or in the opposite meridian, as the resultant of the magnetic forces, though they may be changed in intensity, will not be changed in direction. In like manner, if various discharges take place simultaneously or successively, there will be certain places where the direction of the resultant forces is not changed, and other places where the change of direction is a maximum. A universally suspended needle, however, will have its direction always changed, unless when the disturbing cause is in the direction of its axis, or in a plane perpendicular to that axis. Hence, then, it is easy to understand (nay, the fact is a necessary result of our hypothesis) why there are auroræ which disturb and auroræ which do not disturb the needle, why distant auroræ affect it when nearer ones do not, and why the needle is in a shivering or constantly oscillating state during auroræ in which the places where the magnetic atmosphere is disturbed are constantly changing. In the same manner, we may account for the influence on the needle, observed by Sir Everard Home and Sir George Back, during the prevalence of a thunder storm, while the electricity of the atmosphere destroys by its action the magnetic equilibrium, when this action is not compensated by an equal one on the opposite side of the magnetic meridian. When such a compensation takes place, the needle will not deviate from its mean position, though the number of its vibrations in a given time may be altered.

Among the other causes which have a tendency to disturb the magnetic needle, we may enumerate earthquakes and volcanic eruptions, all of which are accompanied in general with electrical phenomena. In 1767 Daniel Bernoulli observed the dip of the needle to diminish half a degree during an earthquake; and De la Torre observed changes of several degrees in the variation of the needle during an eruption of Vesuvius.

In treating of the periodical disturbances, or irregular changes, in the variation of the needle, Dr Lloyd arrives at the conclusion that there are probably *two classes* of disturbances, the results of distinct physical causes, one of which is periodical, and the other wholly irregular; the former being *local* (depending on the time at the place of observation) and the latter *universal.* The principal, if not the only one, of the periodical disturbances, occurs a few minutes before ten P.M., and causes the north pole of the magnet to deviate to the east. Its mean magnitude is 10′·0 and its mean duration an hour and a half.

SECT. II.—*On the Dip or Inclination of the Needle.*

Dip of the needle.

The dip or inclination of the needle is, as we have already had occasion to observe, the angle which a well-balanced needle forms with the horizon after it is rendered magnetic, and when it has the power of free motion in the plane of the magnetic meridian, as shown in fig. 59, where NS is the needle balanced on a horizontal axis, at right angles to its length.

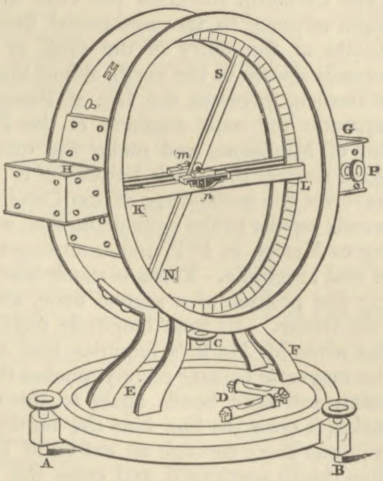

Fig. 59.

The dip of the needle, like the variation, has different values in different parts of the globe; generally speaking, being nothing, or horizontal, near the equator, and 90°, or perpendicular to the horizon, at the magnetic poles. The line passing round the globe near its equator, in every part of which the dip is nothing, is called the *magnetic equator*, which is a very irregular line, crossing the equator at *four* points, as shown in the annexed figure, where the black line E E is the real equator, and the dotted line MMM the magnetic equator, which is seen to cross the other at four points, in place of two.

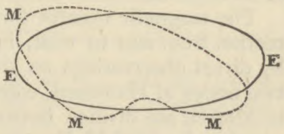

Fig. 60.

The general inclination of the magnetic to the terrestrial equator is about 12°, its principal intersections or nodes being placed in 113° 14′ west longitude and 66° 46′ east longitude from Greenwich; and it is a tolerably regular line throughout one-half of its circumference in the Atlantic and Indian Oceans. In discussing the observations made by Cook and others in the South Sea, M. Biot has shown that the above elements are incorrect everywhere beyond the western node, between 115° and 270° west longitude; and he concludes that between 256° and 158° 50′ of west longitude it again cuts the terrestrial equator at least once, which renders it necessary that it cut it another time near the east coast of Asia, provided it is found in the Atlantic Ocean or the south latitude. Hence there will be at least three nodes, and perhaps four, as shown in the preceding figure. This singular inflexion of the magnetic equator in the South Sea has been confirmed by the more recent observations of M. Freycinet.

Morlet and Hansteen.

The exact position of these nodes, and the true form of the magnetic equator, were determined with great care by MM. Morlet and Hansteen. There are some slight differences between their results, which have been pointed out by Arago, in the following excellent summary of the results of their inquiry:—Both Morlet and Hansteen place the magnetic equator wholly to the south of the terrestrial equator, between Africa and America; its greatest southern latitude being at 25°, one node is in Africa, in about 22° of east longitude, or in 18° according to Morlet. In setting out towards the east from this node, which is nearly in the centre of that part of the African continent, the magnetic equator advances rapidly to the north of the terrestrial equator, quits Africa a little to the south of Cape Guardafui, and in the Arabian Sea it attains its most northerly latitude of about 12°, in 62° of east lon-

Morlet and Hansteen.

gitude. Between this meridian and 174° east, the magnetic equator is constantly to the north of the equinoctial line. It cuts the Indian Peninsula a little to the north of Cape Comorin, traverses the Gulf of Bengal, making a slight advance to the equinoctial, from which it is only 8° distant at the entry of the Gulf of Siam. It then reascends a little to the north, almost touches the north point of Borneo, traverses the Isle of Paragua, the strait which separates the most southern of the Philippines from the Isle of Mindanao, and under the meridian of Naigiou it again reaches the north latitude of 9°. From this point it traverses the archipelago of the Caroline Islands, and descends rapidly to the equinoctial line, which it cuts, according to Morlet, in 174°, and according to Hansteen in 187°, of east longitude. There is much less uncertainty respecting the position of a second node, also situate in the Pacific Ocean. Its west longitude ought to be about 120°; but while M. Morlet's inquiries lead him to conclude that the magnetic equator merely touches the equinoctial at that point, and then bends again to the south, M. Hansteen makes it cross the line into the northern hemisphere, and continue there through an extent of 15° of longitude, and then return southward, and cross the equinoctial again in about 108° of west longitude, or 23° from the west coast of America. This discrepancy between the deductions of Morlet and Hansteen is, after all, very trivial; for, in the case just mentioned, the magnetic equator does not go more than 1½° to the north of the equinoctial; and, in general, the magnetic equator of Morlet differs in no part so much as 2° in latitude from that of Hansteen.

The magnetic equator thus traced over the globe has a motion from east to west, in so far as can be determined by direct observations on the position of its nodes. The two nodes of Hansteen, corresponding to the tangent node of Morlet, are divided between 108° and 126° of west longitude. In 1819 M. Freycinet found, on board the Uranie, that this node was in 132° of longitude; and General Sabine found that the node in Africa, which was far from the coast in 1780, had advanced from east to west even to the Atlantic Ocean. M. Morlet had indicated, with some distrust, this motion of the magnetic equator; and he considered it probable that its form and position regulated the direction of the annual variations of the needle. He found that the dip of the needle diminished wherever the motion of the equator tended to diminish the magnetic latitude, and that it increased, on the contrary, wherever the magnetic latitude was increased; a result which was confirmed by future observations.

Admiral Duperrey.

Much light has been thrown on the subject of terrestrial magnetism, but particularly on the form and motion of the magnetic equator, by the observations of Admiral Duperrey, made on board the Coquille, in the years 1822–1825. This vessel crossed the magnetic equator six times, and Duperrey was able to determine directly two of its points, situate in the Atlantic Ocean. On the chart of M. Morlet, and in that of Hansteen, the latitudes of those parts which correspond to the same longitudes are greater by 1° 43′ and and 1° 50′; and hence Arago concluded that the magnetic equator has approached the terrestrial equator by the same quantities. In the South Sea, near the coast of America, Duperrey determined two points of the magnetic equator. On the charts of Morlet and Hansteen the latitudes of these points is about a degree smaller, but the difference is in a direction contrary to that which was found in the Atlantic Ocean; from which it follows, that near the coast of Peru the magnetic equator has removed from the equinoctial line.

In discussing the magnetic observations made on board the Coquille, Duperrey has traced the form of the magnetic equator with an unexpected degree of accuracy; employing the formula of Barlow, which makes the tangent of the magnetic latitude equal to half the tangent of the dip, and making one only of dips which do not exceed 30°. Having obtained the magnetic latitudes of the places where the observations were made, he deduces, both from these and from the variation of the needle at the same place, the changes in longitude and latitude, which, being combined with the geographical positions of the stations, give him the co-ordinates of the corresponding points of the magnetic equator. By means of this method, and relying only on his own observations, he has traced a portion of this curve through an extent of 247° of longitude, comprehending the Atlantic Ocean, a part of South America, the great equinoctial ocean, and the Asiatic archipelago, as far as the western extremity of the island of Borneo. In prolonging the magnetic equator to the east, he has used the observations of General Sabine in 1822, made in the island of St Thomas, in the Gulf of Guinea. Between the west of Borneo and the north of Ceylon, he availed himself of the observations made in 1827 by M. de Blosseville, in the Chevrette. Adopting General Sabine's determination of one of the nodes of the magnetic equator, which he places 3° 20′ to the east of the meridian of Paris, not far from the west coast of Africa, Duperrey shows that this equator, after resting at this node, rises to the north, traverses Africa, and reaches probably 15° of north latitude, in the Red Sea (as appears from an observation made by Pantin in the Isle of Socotra in 1776). It then descends a little to the south, to join a point in it fixed by M. Blosseville in the north of Ceylon. From these facts it appears, *that the magnetic equator will meet the equinoctial line only in two points, which are diametrically opposite, the one situate in the Atlantic Ocean, and the other in the great ocean nearly in the plane of the meridian of Paris. When this equator meets only some scattered islands, it recedes only a little from the equinoctial line. When the islands are more numerous, it recedes farther; and it reaches its maximum deviation in both hemispheres only in the two great continents which it traverses. He found also, that between the northern and southern halves of the magnetic equator, there is a symmetry very remarkable, and much more perfect than had been previously believed.* These results are laid down by Duperrey in a chart of the equatorial regions published in the *Ann. de Chimie* for 1830.

The dip of the needle increases on each side of the magnetic equator, and Hansteen has projected the lines of equal dip in his chart already referred to. These lines are nearly parallel to the magnetic equator, till we reach 60° of north latitude, and they then begin to bend round the American magnetic pole, which Commander Ross found to be situate in north latitude 70° 5′ 17″, and west longitude 96° 45′ 48″, the needle having at this point, in Boothia Felix, lost wholly its directive power, and the dip being 89° 59′, within a minute of 90°. Had we inferred the position of the needle from the form of the magnetic equator, we should have placed it in 25° of west longitude, viz., the meridian in which the magnetic equator advances farthest to the south, or about 13½°, and in 76½° of north latitude, or 90° – 13½°. This, however, as all the arctic observations prove, is not the case; and we are led by the phenomena of the dip, as well as by those of the variation in different points of the globe, to conclude that every place has its own magnetic axis, with its own pole and its own equator, as already stated by Mr Barlow.

The following table contains the best observations on the dip of the needle, as collected by Professor Hansteen, and also the magnetic intensities from the equator to the poles:—

Places of Observation.	Dip.	Intensity.	Places of Observation.	Dip.	Intensity.	Places of Observation.	Dip.	Intensity.

On the Progressive Change in the Dip of the Needle.

Progressive change in the dip.

The dip of the needle, like the variation, undergoes a continual change, increasing in some parts of the world, and diminishing in others. The following table shows the change which has taken place in the dip at Paris from 1671 down to 1829:—

Year.	Dip.	Year.	Dip.
1671	75° 0′	1818	68° 35′
1754	72 15	1819	68 25
1776	72 25	1820	68 20
1780	71 48	1821	68 14
1791	70 52	1822	68 11
1798	69 51	1823	68 8
1806	69 12	1824	68 7
1810	68 50	1825	68 0
1814	68 36	1826	68 0
1816	68 40	1829	67 41 Arago.
1817	68 38		

The following table shows the changes of the dip at London from 1720 to 1833:—

Year.	Observed.		Computed
1720	74° 42′	Graham.	76° 27′
1773	72 19	Heberden.	73 40
1780	72 8	Gilpin.	73 18
1790	71 53	Ditto.	72 39
1800	70 35	Ditto.	71 58
1810	...	...	71 15
1818	70 34	Kater	70 34
1821	70 3	Sabine.	...
1828	69 47	Ditto.	69 43
1830	69 38	Kater.	...
1833	...	...	69 21

The last column in the table was calculated by Professor Barlow, by his formula, $2\ \text{cotan}\ \pi L = \text{tan. dip}$, or that the tangent of the dip is equal to double the tangent of the magnetic latitude.

The progressive variation in the dip of the needle is, as Humboldt has shown, the necessary consequence of a change in the magnetic latitude, arising from the motion of the nodes of the magnetic equator modified by the form of this curve; and M. Morlet applied the same principle to account for the variations of the dip in different parts of the globe.

Humboldt and Arago have endeavoured to deduce the annual diminution of the dip occasioned by the motion of the magnetic equator. By comparing the observations of 1778 and 1810 for Paris, the annual diminution was about 5′, whereas, from those of 1820 and 1825, it appears to be only 3′·3. The observations at Turin from 1805 to 1826 give 3′·5, and those of Florence 3′·3.

Besides the progressive variation of the dip, Hansteen has found, from a series of observations made with a dipping needle by Dollond, that the dip during the summer was about 15 minutes greater than during the winter, and about 4 or 5 minutes greater in the forenoon than in the afternoon.

SECT. III.—*On the Intensity of Terrestrial Magnetism.*

Intensity of terrestrial magnetism.

The determination of the intensity of the earth's magnetism at different points of its surface, and of the changes which it undergoes either progressively, or at different times of the day, and different seasons of the year, has become one of the most important practical problems connected with the physical condition of the globe.

The method of determining this important element by the number of oscillations of the needle was first suggested by Graham, and brought to perfection by Coulomb, Humboldt, and Hansteen. Observations on the dip and magnetic intensity were made between 1791 and 1794 at Brest, Teneriffe, Van Diemen's Land, Amboyna, and Surabaya. They were published in the second volume of the *Voyage d'Entrecarteaux* in search of Laperouse. If a needle whose axis of suspension passes through its centre of gravity, and which has its north polar and south polar magnetism equal, and similarly distributed, is made to vibrate by turning it from its position, and allowing it to receive that position by a series of oscillations, it is obvious that the earth's magnetism acts with equal force on each half, and that both these forces tend to draw the needle into the magnetic meridian. The greater the magnetic force, the more quickly will the needle oscillate and recover its primitive position. The needle is, in short, in the same circumstances as a pendulum oscillating by the action of gravity; and, as in this case, the forces are as the squares of the number of oscillations made in the same time.

Let us now suppose, to take the simplest case, that we make the dipping needle oscillate in the plane of the magnetic meridian, round the line of the dip, and that when the experiment is performed at the equator, the number in a second is 24, while in another place it is 25; then the intensities of the magnetic force at these places is as 25^2 to 24^2, or as 625 to 576, or as 1·085 to 1·000. By carrying the same needle to different parts of the earth, the magnetic intensity at these places will be found from the number of its oscillations.

In the application of this method there are various practical difficulties, particularly the necessity of its resting upon knobs, edges of steel, or agate, during its oscillation, which do not exist if we make a needle oscillate horizontally when suspended by a fine fibre of silk. This latter method has, therefore, been the one universally employed, though a little calculation is necessary to obtain the intensity of terrestrial magnetism from the number of oscillations which are performed.

Let NS be a magnetic needle suspended horizontally by a fibre of silk P, and let NC be the line of the dip, or ANC=D the dip itself. Then if F is the force of terrestrial magnetism acting upon the oscillating needle, and tending to bring it to rest, we may decompose this force into two, viz., one, NB, acting in a vertical direction, and which, being counteracted by the suspended force, has no tendency to affect the needle; and the other, NA, acting horizontally, and tending to direct the needle, and cause it to oscillate. This force NA is the cosine of ANC, the dip D. Hence the force NA will be equal to F × cos D. For any other place where the magnetic intensity is F′ and the dip D′, the effective force will be F′ × cos D′; and if we call N the number of oscillations made in a second at the first place, and N′ the number at the second, we shall have $F \times \cos D : F' \times \cos D' = N^2 : N'^2$, and the ratio of the magnetic intensities at the two places, or

$$\frac{F}{F'}=\frac{N^2 \cos D}{N'^2 \cos D'}.$$

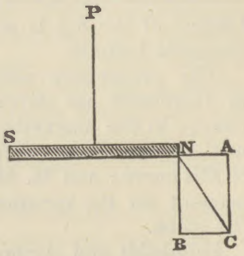

Fig. 61.

In this way observations on the magnetic intensity have been made in almost every part of the world, and a table containing upwards of 300 results, obtained principally by Professor Hansteen and his friends, was drawn up by himself, and republished in the last edition of this work. It contained the number of seconds in which 300 vibrations of the needle were performed, and the longitude and latitude of the places of observation. At that time these observations had not appeared in any English work, and had therefore a peculiar value; but we have not reprinted them, as a much more extensive and correct table of the actual magnetic intensities has been recently drawn up by General Sabine, and printed in the *Seventh Report of the British Association.*

The principal intensities computed from Hansteen's observations will be found in our table of the dip given above.

It appears from these data that the magnetic intensity increases from the equator to the poles, and the law of variation is shown in the following table:—

Dip of the Needle.	Magnetic Intensity.	Dip of the Needle.	Magnetic Intensity.
0°	1·0	73	1·4
24	1·1	76⅔	1·5
45	1·2	81	1·6
64	1·3	86	1·7

Professor Hansteen projected upon a map of the globe the lines passing through all the places in which the intensity has the same value. These lines he calls *isodynamic lines*, or those of *equal force*, and they are, generally speaking, nearly parallel to each other, and to the lines of equal dip.

Hansteen's observations in Siberia.

Many valuable observations on the intensity of the earth's magnetism were made during the numerous arctic expeditions which were sent out by the British government; but Professor Hansteen being extremely desirous of establishing, by direct observations of his own, the existence of the secondary magnetic pole, which he believed existed in Siberia, set out for this purpose in 1827, at the expense of the Norwegian Storthing, and with every encouragement and assistance from the Russian government. The results of this expedition exceeded his most sanguine expectations. The Russian Academy of Sciences were, in consequence of Professor Hansteen's scientific journey, induced to take a new interest in the subject of terrestrial magnetism, which exhibits such interesting features throughout the Russian empire; and the Russian government has since established regular observatories in different parts of its vast dominions, for making magnetical experiments. The Russian empire is actually traversed by *two* lines of no variation, and it is proposed to determine with great precision, every ten years, the exact position of these two lines. Near the first of them, which traverses European Russia, Petersburg, Moscow, and Kasan, are situate; and near the second, which passes through Siberia, are situate Kiachta and Nizni-Oudinsk.

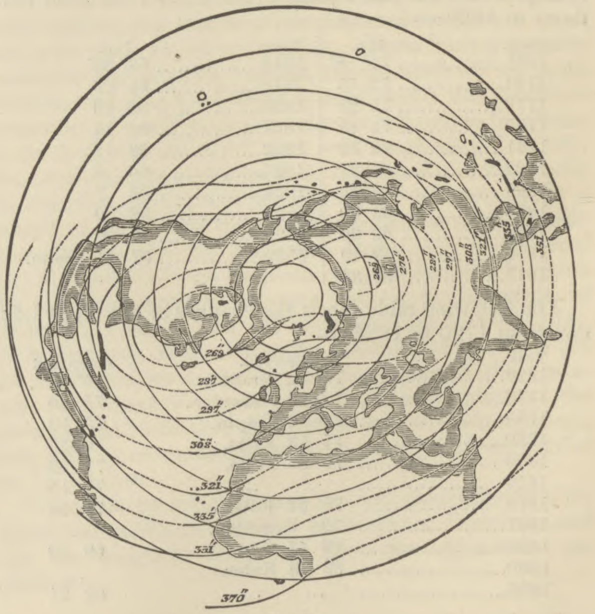

Fig. 62.

The principal observations made by Hansteen in Siberia have been laid down in a map of the northern hemisphere by General Sabine, along with other observations made by himself and Humboldt. In this map, of which the prefixed figure is a copy, it is exceedingly interesting to observe the isodynamic lines surrounding the two northern magnetic poles, and forming a series of returning curves similar to lemniscates, and which may be calculated by the formulæ of Sir David Brewster, already given in the History of Magnetism.

In this map the *American* pole is situated nearly in 60° of N. Lat. and 80° of W. Long.; and the *Asiatic* pole in 60° N. Lat. and 100° of E. Long. The black lines pass through the places where the magnetic intensity was observed to be equal, and the dotted parts of the same curves indicate the probable direction of the lines where observations had not been made. The lines round the American pole are laid down principally from General Sabine's observations, and those round the Asiatic pole from the later observations of Hansteen. The following is the account given by General Sabine of the different isodynamical lines in the figure:—

The *first* curve, or that nearest the magnetic poles, is that in which a magnetic needle which performs *n* oscillations in 300^s in London, performs the same number in 269^s round the Asiatic pole. This curve contains a smaller space than the corresponding curve round the American pole, which proves the inferior activity of the former pole. Hansteen traced the S. part of this curve below Lat. 60°, from the River Yenisei to 115° of W. Long.; that is, 25° beyond the Yenisei, and to Lat. 60°, where it takes a direction almost due north.

The *second* curve, or that in which the same number *n* oscillations are performed in 278^s, goes round both the American and Asiatic poles, including both within its area. It passes to the N.W. of Melville Island, and to the N.E. of some stations on the W. coast of Greenland; and it cuts the American coast between the Havannah and New York. Dr Erman, who accompanied Hansteen into Siberia, traced the same curve from the embouchure of the Oby, in N. Lat. 68°, and E. Long. 70°, following the direction of the River Mina as far as 60° N. Lat. The curve here gradually bends to the E., and after passing between Tobolsk and Narym, it was again detected by M. Hansteen at Kainsk, a few degrees to the S. of Lake Baikal.

The *third* curve, or that in which *n* oscillations are performed in 287^s, is drawn on the American side, from observations made at the Havannah, at the Pendulum Isle on the E. coast of Greenland, in N. Lat. 74° 5′ and between Spitzbergen and Hammerfest, near the North Cape. This curve, according to Hansteen, enters Europe between Archangel and Nova Zembla; and he met with it again between Moscow and Tobolsk, at 56½° of E. Long. and 57½° of N. Lat.

The *fourth* curve, or that in which *n* oscillations are performed in 297^s, passes near Jamaica, where the oscillations were performed in 294^s, and, after traversing the N. of Britain, it enters Norway to the S. of Bergen. Advancing eastward, it passes between Stockholm and Tornea, and thence by St Petersburg and Moscow.

The observations of Professor Hansteen do not extend farther S. than these lines, and therefore General Sabine has laid down in the map the line in which *n* oscillations are performed in 308^s, 321^s, 335^s, 351^s, and 370^s, from his own observations and those of Humboldt. The lowest number of seconds in which *n* oscillations are performed is at the magnetic poles, where it is nearly 262 or 263, and the greatest, 370, the time in which they are performed at the equator.

We have stated that the isodynamical lines are nearly parallel to those of equal dip. This is the case in Scotland; but towards the E., in Norway and Sweden, the lines of equal intensity bend more to the N., and cut the former; and also, under the same line of equal dip, the intensity is weaker to the E. than to the W. Hence Professor Hansteen found that the pole of the lines of equal dip lies in 71° of Lat., and 102° of Long., while the pole of intensity is in 56° of Lat., and 80 of Long. W. of Paris. The first of these determinations coincides very nearly with the pole of Sir James Ross, where the dip was 90°. The observations made during the arctic expeditions from England, and also those by Hansteen and Erman in Siberia, prove beyond a doubt the accuracy of the earlier conclusion of Hansteen, that the lines of equal intensity and equal dip are not parallel. Humboldt discovered the node of the magnetic equator with the isodynamical curve in 7° of S. Lat., and 81° of Long. W. of Paris. He traced this last line to the W. of the Cordilleras of the Andes, and along the coast of Peru, towards Kasma and Fluormay, even to the 10th degree of S. Lat. M. Adolphus Erman found in Siberia, that the isodynamic line, where the intensity is 1·60 (that of the equator being 1·00), directs itself also from N. to S. with a slight inclination to the S.E. He observed this line *cut almost at right angles the curves of equal dip*, and then descend from the N.N.W. to the S.S.E., from Ochotsk, near the mouths of the Oby, to Tomsk. Humboldt is of opinion that the isodynamical line and the Peruvian node of the magnetic equator have been carried, since his voyage, from E. to W.; and he informs us that M. A. Erman, in the 135th degree of Long. W. of Paris, and in the magnetic equator, found that the intensity of the magnetic forces was sensibly the same as he had found them twenty-six years before on the magnetic equator in Peru.

As the intensity of terrestrial magnetism at different places is not a function of the dip at these places, and the isodynamic lines are not parallel to those of equal dip, it is probable that different points of the equator have not the same magnetic intensity. "Having carried," says Humboldt, "the same needle or needles compared with them, from Paris to Mexico, to the magnetic equator in Peru, to Berlin, to Petersburg, to the shores of the Caspian, and to the N. of Asia, I have expressed the magnetic intensities at these places, by taking for unity the intensity which I find on the magnetic equator in Peru, or rather in the intersection of this equator with the isodynamical line of minimum intensity. On this supposition, I find for Paris 1·3482, for Milan 1·3121, for Naples 1·2745. The very valuable observations of M. Rossel, at Surabaya in Java, and those of General Sabine near St Thomas, 5° N. of the equator, indicate that the magnetic intensity is less on the magnetic equator near the W. coast of Africa (W. Long. 40° 24′), and in the great Italian archipelago, than in the portion of the magnetic equator which crosses Peru. Besides, M. A. Erman has observed, that on the E. coasts of South America the intensities are much weaker at the same distances from the S. terrestrial pole than on the W. coasts. The intensity 1·00, found to the W. of the new continent, on the magnetic equator in the South Sea, in 135° of W. Long., and 1° 55′ of S. Lat., shows itself on the coasts of Brazil towards the 38th degree of S. Lat., while the dip is there even more than 37° S. It appears to me more probable that the minimum intensity at the surface of the earth is to the maximum, not as 1 to 1·6 or 2, as has been supposed, but even much beyond the ratio of 1 to 2·6."

Observations are yet wanting to determine in what manner the intensity varies with the height. Humboldt is of opinion that it decreases, thus confirming the deductions of Kupffer.

By combining all the observations of intensity from 179° to 183°, Professor Hansteen came to the conclusion, *that the total magnetic intensity is smaller in the southern than in* *the northern hemisphere.* Admiral Duperrey confirmed this result. According to the investigations of Biot, the natural magnetic intensity, or I, is $= 2A \cdot \sqrt{\frac{1}{4 - 3\sin^2 \delta}}$, and that of the horizontal needle $= 2A\sqrt{\frac{1}{3 + \sec^2 \delta}}$, δ being the dip; but these formulæ presuppose that the earth is perfectly homogeneous, and of course they cannot be verified by insulated observations. Admiral Duperrey was therefore obliged, in order to bring all these observations into this state, to take the mean intensity of the terrestrial equator and of each of the parallels of the globe, and to multiply the circumference of each curve by its intensity in order to have the total intensity, and then to take the mean of the total intensities of the corresponding parallels in each hemisphere. In this manner he obtained all the points of the curve which represents the law of the increase of the magnetic forces from observation. The curve thus traced, when compared with that which is calculated by the formula of M. Biot, does not deviate from it above 0·015 of the intensity, supposing the intensity at the magnetic equator in Peru to be 1. He found also that the surface of the north magnetic hemisphere is to that of the south one in the ratio of 1·0000 to 1·0152, a ratio which is the same as that of the total intensity of the south terrestrial hemisphere to the total intensity of the north terrestrial hemisphere; and he hence concludes, that *the surfaces of the two magnetic hemispheres are proportional to the intensities of the two terrestrial hemispheres.*

The lines of equal magnetic intensity had the values 0·9, 1·0, 1·1, 1·2, &c., given to them in reference to an arbitrary unit, which was the measure of the force at the place in South America when Humboldt measured it early in the present century. Compared with this measure, the intensity in Paris was 1·348, and that in London 1·372. This arbitrary scale, however, though useful in bringing together the results obtained by different observers, assumed that the magnetic force was constant at the same place, whereas all the three magnetic elements are subject to change. Poisson first pointed out a method of surmounting this difficulty; but Gauss, in his work entitled *Intensitas vis Magneticæ*, already referred to, explained and introduced a method of determining the absolute magnetic intensity at the place where the experiment is made, expressed in terms of standards of weight and linear measure, and recognised subdivisions of time. As the absolute values of the intensity have the same relation to each other as the arbitrary values, it is necessary only to have the values of the two scales at one station to enable us to convert the one into the other at all other places.

The first general map of the isodynamic lines was laid before the British Association in 1837 by General Sabine; but he afterwards adapted it to 1840, and in the revised state he has published it in his admirable article forming plate 23 in the new edition of Johnston's *Physical Atlas*, just published. The lines are numbered on the arbitrary scale, but the relative absolute values, which are as follows, are given on the map:—

Arbitrary scale.	Absolute scale.	Arbitrary scale.	Absolute scale.
0·9	6·81	1·6	12·11
1·0	7·57	1·7	12·87
1·1	8·32	1·8	13·62
1·2	9·08	1·85	14·00
1·3	9·84	1·9	14·37
1·4	10·60	2·0	15·14
1·5	11·35	2·05	15·52

The first of these numbers, viz., 0·9, corresponds with the equatorial intensity in the Atlantic; and the last of them, viz., 2·05, with the maximum observed intensity in S. Lat. 60., and E. Long. 170. to 150.

In order to discover the causes of terrestrial magnetism, the localities in which they operate, and the laws which regulate the periodical changes which have been observed, maps of the three magnetic elements must be constructed in every part of the globe. The determination of these elements for the British Islands was undertaken in 1834, at the suggestion of the British Association, by General Sabine, Dr Lloyd, Sir James Ross, Mr Phillips, and Mr W. Fox, who published the result of their observations in the Reports of that body for 1838.[1] General Sabine proposes, that as 20 years have now elapsed, the observations should be repeated; and we would suggest that they should be made at the bottom of mines and the top of mountains.

Dr Kreil has made similar observations in 1846–54 in the Austrian States, and Dr Lamont in and around Bavaria in 1849–53. The Messrs Schlagintweit are occupied in the same work in British India; and Dr Bache in the United States of America, Captain Elliot in the Indian Archipelago, and Mr Vogel in Northern and Central Africa, at the expense of the British government.

On the Monthly and Daily Change of Intensity.

Monthly and daily changes of intensity.

The magnetic intensity, like the other elements of terrestrial magnetism, suffers monthly and diurnal changes. By means of the vibrations of a needle delicately suspended, M. Hansteen found that the *minimum* of the daily change of intensity is between ten and eleven in the forenoon, and the *maximum* between four and seven in the afternoon in May, and about seven in June. The intensity is a maximum in December, and a minimum in June. The greatest monthly change in the intensity is a maximum in the months of December and June, about the time when the earth is in its perihelion and aphelion. It is a minimum near the equinoxes, or when the earth is at its mean distance from the sun. The greatest daily change is least in the winter and greatest in the summer; the greatest difference of the annual change of intensity is 0·0359. Professor Hansteen likewise found that the magnetic intensity is diminishing in Europe, and that the decrease is greater in the northern and eastern, than in the southern and western parts, an effect which he conceives to be produced by the motion of the Siberian pole towards the east. At Port Bowen, Sir Edward Parry observed an augmentation of the magnetic intensity to take place from the morning till the afternoon, and a diminution of it from the afternoon till the morning. The results of Hansteen were also confirmed by Mr Christie,[2] who showed that the terrestrial magnetic intensity is a minimum between ten and eleven o'clock in the morning, the time nearly when the sun is in the magnetic meridian; that it increases from this time until between nine and ten o'clock in the evening, after which it decreases, and continues decreasing during the morning, till it reaches its minimum between ten and eleven. These results were deduced from observations made in May, *within doors*, to determine the positions of the points of equilibrium at which a magnetic needle was retained at different hours during the day, by the joint action of two bar-magnets and of terrestrial magnetism, reduced to their true positions at the standard temperature (60°) of the magnets. As this change in the position of these points was produced by the change in the magnetic intensity, Mr Christie thus obtained accurate measures of the last of these elements by means of the following formula:—

---

[1] This report was published separately, entitled *Report on the Magnetic, Isoclinal, and Isodynamic lines in the British Islands.* Lond. 1839.

[2] *Phil. Trans.*, 1825, p. 49-51.

Terrestrial Magnetism.

$$M - F\,(\cdot004690814 + \cdot000829329 \cos^2 \varphi) = 0;$$

in which M is the horizontal part of the terrestrial magnetic force, acting on the north arm of the needle in the line of the dip, F the force with which a pole of the needle is repelled from a pole of the same name of either magnet, or attracted towards that of a contrary name at unity of distance, and φ the angle which the axis of the needle makes with the meridian, or the azimuth of the point of equilibrium.

Mr Christie repeated his observations in *the open air* in June, and from these it appears that the minimum intensity happened nearly at the time the sun passed the magnetic meridian, and rather later than in May, which was also the case with the time of the sun's passage over the meridian. The intensity increased until about six o'clock in the afternoon, after which it appears to have decreased during the evening, and to have been decreasing from an early hour in the morning. Mr Christie has given the following interesting view of Hansteen's results and his own :—

Intensity deduced from Hansteen's Observations in 1820.			Intensity deduced from Mr Christie's Observations in 1823.		
Time.	May.	June.	Time.	May.	June.
8 *h.* 0 *m.* A.M.	1·00034	1·00010	7 *h.* 3 *m.*	1·00114	1·00061
10 30	1·00000	1·00000	10 30	1·00000	1·00000
4 0 P.M.	1·00299	1·00251	4 30	1·00175	1·00223
7 0	1·00294	1·00304	7 30	1·00220	1·00239
10 30	1·00191	1·00267	9 30	1·00231	1·00209

The principal difference between these results is, that in Mr Christie's observations the intensity seems to diminish more rapidly in the morning, and increase more slowly in the afternoon, than it does in those of Hansteen.

The following table shows the horizontal magnetic intensity at Göttingen, as determined by Professor Gauss, in different months of 1832, with great accuracy.

1832.	Horizontal Intensity.	1832.	Horizontal Intensity.
May 21	1·7820	July 25, 26	1·7845
... 24	1·7694	Sept. 9	1·7764
June 4	1·7713	... 18	1·7821
... 24–28	1·7625	... 27	1·7965
July 23, 24	1·7826	Oct. 15	1·7860

In order to obtain from these numbers the absolute magnetic intensity, to compare them with the results in Hansteen's table, they must be multiplied by the secant of 68° 22′ 22″, the dip at Göttingen on the 23d June 1832.

SECT. IV.—*On the Nature and Causes of the Earth's Magnetism.*

Nature and causes of the earth's magnetism.

The phenomena described in the preceding sections afford abundant evidence that the earth is in some way or other magnetic; but what is the nature of its magnetic condition, or from what cause it derives its origin, are points which it is not easy to determine. The earliest and the most natural supposition is that of Dr Gilbert, that the earth contains within itself a powerful magnet, lying in a position which nearly coincides with its axis of rotation. In this case, the pole of this magnet, which acts in our northern hemisphere, must have south-polar magnetism, as it attracts the north pole of the needle; while the pole in the southern hemisphere must have north-polar magnetism, as it attracts the south pole of the needle. That this hypothesis would, generally speaking, represent the ordinary phenomena of terrestrial magnetism, may be easily shown by placing a bar-magnet within a terrestrial globe, and observing the phenomena exhibited by a small needle suspended at its centre of gravity by a fine thread or fibre. As the magnet is placed out of the axis of rotation, the needle in the northern hemisphere will always point to the north end of the inclosed magnet, exhibiting all the phenomena of the variation of the needle, as usually observed.

Terrestrial Magnetism.

Causes of the earth's magnetism.

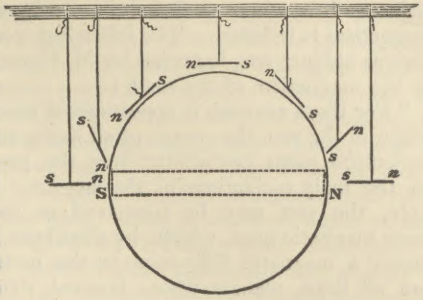

Fig. 63.

The general phenomena of the dip will also be exhibited, as shown in the annexed figure, where NS is the direction of the inclosed magnet, shown by dotted lines, S being the northern magnetic pole, and N the southern, and *ns*, *ns*, small needles suspended by fibres *f*, *f*, *f*. The needle has no dip at the equator, because each pole is equally attracted by the corresponding poles of the inclosed magnet, and at the poles S, N, the dip is 90°, as observed at the northern magnetic pole by Sir James Ross. At latitudes intermediate between the magnetic equator and the magnetic poles, the dip has an intermediate value.

In the same manner as a common bar-magnet communicates magnetism to a piece of soft iron held near it, the supposed magnet in the earth communicates magnetism to a soft iron bar held in the magnetic meridian, and parallel to the dipping needle, which in this country is not far from a vertical position. The soft iron is temporarily a magnet, exactly like the soft bar in the presence of a real magnet, and possesses the very same properties.

In the progress of discovery, however, it has been found that the phenomena of the dip and the variation are more complex than this hypothesis will allow us to suppose; and in measuring the magnetic intensity in Siberia, Hansteen has proved that there is another magnetic pole in that country, which regulates the magnetic phenomena. In order to account for these, we must therefore suppose another magnet passing through the globe in the direction of a diameter whose pole coincides with the Siberian magnetic pole. But even this addition to the hypothesis of Gilbert will not explain the phenomena, unless we resort to the absurd assumption of Halley, who gives rotatory movements to magnetic spheres placed in the interior of the globe.

A more sober and philosophical hypothesis is one which has been long gaining ground, and which later discoveries have rendered still more probable. According to this hypothesis, the magnetism of the earth is not that of a magnet, but that of a sphere or spherical shell of iron on which magnetism is induced. The difference between these two magnetic states is very great. In regular magnets the centres of action are placed at their extremities or poles; but in masses of iron, either hollow or solid, either regular or irregular, the centres of action are always coincident with the centre of attraction of the surface of the mass. When the observations on the variation and dip of the needle became numerous and accurate, philosophers soon perceived that they could not be explained by the action of two magnetic poles at a distance from each other. M. Biot had the merit of first viewing the subject in this light, and he at length came to the conclusion that the nearer the poles were taken to each other, the greater was the agreement between the computed and observed results; and by assuming the two centres as indefinitely near to each other in the centre of the earth, the coincidence between observation and calculation was as great as could be expected. Now, it is a remarkable fact, that Mr Barlow discovered, as we have already seen, that such a coincidence in the centre of action actually takes place in all bodies which are magnetic by induction, such as iron spheres or shells; and he has applied this principle to account for the various phenomena of the dip and variation of the needle. Almost all

Causes of the earth's magnetism.

Hansteen.

the philosophers who have since investigated the subject have adopted this idea; and the only difficulty which attaches to it is, where to find the cause by which the earth's magnetism is induced. The following speculations on this curious subject are hazarded by M. Hansteen, in his work on the magnetism of the earth: —

"For these reasons, it appears most natural to seek their origin in the sun, the source of all living activity; and our conjecture gains probability from the preceding remarks on the daily oscillations of the needle. Upon this principle, the sun may be conceived as possessing one or more magnetic axes, which, by distributing the force, occasion a magnetic difference in the earth, in the moon, and all those planets whose internal structure admits of such a difference. Yet, allowing all this, the main difficulty seems not to be overcome, but merely removed from the eyes to a greater distance; for the question may still be asked with equal justice, *whence did the sun acquire its magnetic force?* And if from the sun we have recourse to a central sun, and from that again to a general magnetic direction throughout the universe, having the milky-way for its equator, we but lengthen an unrestricted chain, every link of which hangs on the preceding link, no one of them on a point of support. All things considered, the following mode of representing the subject appears to me most plausible. If a single globe were left to move alone freely in the immensity of space, the opposite forces existing in its material structure would soon arrive at an equilibrium conformable to their nature, if they were not so at first, and all activity would soon come to an end. But if we imagine another globe to be introduced, a mutual relation will arise between the two; and one of its results will be a reciprocal tendency to unite, which is designated, and sometimes thought to be explained, by the merely descriptive word attraction. Now, would this tendency be the only consequence of that relation? Is it not more likely that the fundamental forces, being driven from their state of indifference or rest, would exhibit their energy in all possible directions, giving rise to all kinds of contrary action? The electric force is excited, not by friction alone, but also by contact, and probably also, though in smaller degrees, by the mutual action of two bodies at a distance; for contact is nothing but the smallest possible distance, and that, moreover, only for a few small particles. Is it not conceivable that magnetic force may likewise originate in a similar manner? When the natural philosopher and the mathematician pay regard to no other effect of the reciprocal relation between two bodies at a distance, except the tendency to unite, they proceed logically, if their investigations require nothing more than a moving power; but should it be maintained that no other energy *can* be developed between two such bodies, the assertion will need proof, and the proof will be hard to find.

"I reckon it possible, therefore, that, by means of the mutual relations subsisting between the sun and all the planets, as well as between the latter and their satellites, a magnetic action may be excited in every one of those globes whose material structure admits of it, in a direction depending on the position of the rotatory axes with regard to the plane of the orbit. Each of the planets might thus give rise to a particular magnetic axis in the sun; but as their orbits make only small angles with the sun's equator and each other, these magnetic axes would, perhaps, on the whole, correspond with the several rotatory axes. Such planets as have no moons would, on this principle, have but one magnetic axis; the rest would, in all cases, have one axis more than they have moons, if those different axes, by reason of the small angles which the orbits of their several moons form with each other, did not combine into a single axis. The conical motions by which the rotatory axes of the planets are carried round the pole of the ecliptic (the precession in the earth), joined to the revolving motion of the orbits about the sun's equator (which occasions the present diminution in the obliquity of the ecliptic), might perhaps, in this case, account for the change of position in the magnetic axis. It would greatly strengthen this hypothesis, if the above great magnetic period, after the lapse of which both axes again assume the same position, should in fact be found to coincide with the period of the precession, which, however, seems a little doubtful."

Such was the state of speculation on this part of the subject when Hansteen published his work on the magnetism of the earth. The poles of our globe were then regarded as the coldest parts on its surface; and no conjecture even had been hazarded regarding the connection between the phenomena of terrestrial temperature and terrestrial magnetism, till Sir David Brewster proved, from an immense number of meteorological observations, that there were in our northern hemisphere two poles of maximum cold; that these poles coincided with the magnetic poles; that the circle of maximum heat, like the magnetic equator, did not coincide with the equinoctial line; that the isothermal lines, and the lines of equal magnetic intensity, had the same general form surrounding and inclosing the magnetic poles and those of maximum cold; and that, by the same formula, *mutatis mutandis,* we could calculate the temperature and the magnetic intensity of any point of the globe. These views we have referred to more fully in the "History of Magnetism."

The monthly and daily changes in the intensity of terrestrial magnetism, and in the dip and variation of the needle, had led Canton and others to ascribe these changes to the action of the sun; and Admiral Duperrey, in his paper on the magnetic equator, demonstrated that the points of this great circle, or those where the magnetic intensity is minimum, are also the warmest points of each meridian, or that the thermal and the magnetic equator are connected, as we had already proved to be the case with the thermal and magnetic poles. Admiral Duperrey likewise attributes the differences in the magnetic intensities of different places to their difference of temperature; and he remarks, that in comparing the isothermal and the isodynamic lines, he found a remarkable analogy in their curvatures, and particularly in the direction of their concavities and convexities. In support of these views, Admiral Duperrey refers to the changes in the daily variation, as following the movements of the sun; and he infers that the southern hemisphere of our globe is a degree colder than the northern hemisphere.

But though it is now placed beyond a doubt, that the phenomena of temperature and magnetism are closely connected, and that the latter are powerfully influenced by the former, yet various questions arise, which it is very difficult to answer.

1. Have the phenomena of terrestrial magnetism an electric origin; that is, is the magnetism developed by electro-magnetic or thermo-magnetic causes? or,

2. Are the phenomena owing to the diffusion of iron or other magnetic metals through the solid mass of our globe, in which magnetism is induced by some exterior cause?

The electro-magnetic hypothesis, which was first stated by Sir David Brewster, was ably supported by Professor Barlow in a paper which appeared in the *Phil. Trans.* for 1831, *On the probable Electric Origin of all the Phenomena of Terrestrial Magnetism;* in which he considers it as probable, "that magnetism, as a distinct quality, has no existence in nature." As all the phenomena of terrestrial magnetism can be explained on the supposition that the magnetic power resides on its surface, it occurred to Mr Barlow, that if he could distribute over the surface of an artificial globe a series of galvanic currents, in such a way that their tangential power should everywhere give a corresponding direction to the needle, this globe would exhibit, while under electrical induction, all the magnetic phenomena of the earth upon a needle freely suspended above it. He accordingly put this idea to the test of experiment in the following manner:—

Barlow's electro-magnetic globe.

"I procured," says he, "a wooden globe sixteen inches in diameter, which was made hollow for the purpose of reducing its weight; and, while still in the lathe, grooves were cut to represent an equator, and parallels of latitude at every $4\frac{1}{2}°$ each way from the equator to the poles; these grooves were about an eighth of an inch deep and broad; and lastly, a groove of the same breadth, but of double the depth, was cut like a meridian, from pole to pole, half round. These grooves were for the purpose of laying in the wire, which was effected thus:—The middle of a copper wire nearly ninety feet long, and one-tenth of an inch in diameter, was applied to the equatorial groove, so as to meet in the transverse meridian; it was then made to pass round this parallel, returned again along the meridian to the next parallel; then passed round this again; and so on, till the wire was thus led in continuation from pole to pole.

"The length of wire still remaining at each pole was bound with varnished silk to prevent contact, and then returned from each pole along the meridian groove to the equator. At this point, each wire being fastened down with small staples, the wires of the remaining five feet were bound together to near their common extremity, where they opened to form two points for connecting the poles of a powerful galvanic battery.

"When this connection was made, the wire became of course an electric conductor, and the whole surface of the globe was put into a state of transient magnetic induction; and consequently, agreeable to the laws of action above described, a neutralized needle freely suspended above such a globe would arrange itself in a plane passing from pole to pole through the centre, and take different angles of inclination, according to its situation between the equator and either pole.

"In order to render the experiment more strongly representative of the actual state of the earth, the globe, in the state above described, was covered by the gores of a common globe, which were laid on so as to bring the poles of this wire arrangement into the situation of the earth's magnetic poles, according to the best observations we have for this determination. I therefore placed them in latitude 72° N. and 72° S., and on the meridian corresponding with longitude 76° W., by which means the magnetic and true equators cut one another in about 14° E., and 166° W. longitude.

"The globe being thus completed, a delicate needle must be suspended above it, neutralized from the effect of the earth's magnetism, according to the principle I employed in in my observations on the daily variation, and described in the *Philosophical Transactions* for 1823; by which means it will become entirely under the superficial galvanic arrangement just described. Conceive now the globe to be placed so as to bring London into the zenith, then the two ends of the conducting wire being connected with the poles of a powerful battery, it will be seen immediately that the needle, which was before indifferent to any direction, will have its north end depressed about 70°, as nearly as the eye can judge, which is the actual dip in London; it will also be directed towards the magnetic poles of the globe, thereby also showing a variation of about 24° to 25° to W., as is also the case in London. If now we turn the globe about on its support, so as to bring to the zenith places equally distant with England from the magnetic pole, we shall find the dip remains the same; but the variation will continually change, becoming first zero, and then gradually increasing to the eastward, as happens on the earth. If again we turn the globe so as to make the pole approach the zenith, the dip will increase, till at the pole itself the needle will become perfectly vertical. Making now this pole recede, the dip will decrease, till at the equator it vanishes, the needle becoming horizontal. Continuing the motion, and approaching the south pole, the south end of the needle will be found to dip, increasing continually from the equator to the pole, where it becomes again vertical, but reversed as regards its verticality at the north pole."

Barlow's electro-magnetic globe.

Although the artificial globe represents very exactly on a small scale all the phenomena of terrestrial magnetism, and although, as Mr Barlow says, "he has proved the existence of a force competent to produce all the phenomena, without the aid of any body usually called magnetic;" yet he acknowledges that, "we have no idea how such a system of currents can have existence on the earth, because, to produce them, we have been obliged to employ a particular arrangement of metals, acids, and conductors." The discovery of Dr Seebeck, however, that the mere application of heat to a circuit composed of two metals[1] is capable of developing the magnetic effects above described, is regarded by Professor Barlow as bringing us a step nearer to an explanation of the earth's magnetism, by referring us to nature as the great agent of all these phenomena, and he conceives that only one link is wanting to complete the explanation. This link, however, is a very important one, and we are just as much puzzled to discover the metallic thermo-magnetic apparatus, as we are to discover the electro-magnetic one. If it could be shown that the action of solar heat is capable of developing magnetism in particles such as those which are known to constitute our globe, the great difficulty would be removed; but until this is done, we are disposed to lean to the old though not yet exploded notion, that terrestrial magnetism is the effect of magnetic or ferruginous materials, which are disseminated through the mass of the earth. This leads us to consider the second question relative to the origin of terrestrial magnetism.

2. Are the phenomena owing to the diffusion of iron or other magnetic metals through the solid mass of our globe, on which magnetism is induced by some exterior cause?

In so far as our knowledge extends, iron and other magnetic metals are not so regularly diffused as to produce the magnetic phonomena; and we are not entitled to assume the existence of any regular metallic nucleus, or regular arrangement of metallic strata, capable of producing that uniform action in the magnetic needle which is indicated by the regularity of the isodynamical lines, or those of equal magnetic intensity. That there are actual magnets within the crust of our globe, and abundance of ferruginous matter capable of producing locally magnetic phenomena, cannot be doubted; but the action of these two classes of bodies is regulated by different laws, and we can only regard them as exercising a disturbing force in rendering irregular the action of some more general cause. If the ferruginous matter which produces magnetism is situated near the surface of the earth, we should expect a diminution in the intensity when the needle is made to oscillate above the deepest parts of the ocean, where the solid crust may be many miles distant. If it is, on the other hand, deeply seated, the intensity ought to diminish greatly as we ascend in balloons, or to the tops of our highest mountains; but none of these effects are observed, and it becomes therefore very improbable that the magnetic phenomena are produced either by ferruginous matter *near the surface, or far removed from it.*

But though we cannot find the seat, or rather the intermedium, of terrestrial magnetism in the bowels of the earth, may we not, as a last resource, seek for it *in our atmo-*

---

[1] Mr Sturgeon of Woolwich produced similar effects by the application of heat to only one metal, viz., a rectangle of bismuth only.

Terrestrial magnetism supposed to reside in the atmosphere.

sphere? It appears to be demonstrated by the experiments of Fusinieri, of which we have given a full account in our article on ELECTRICITY, that metals, and *particularly iron*, exist in a state of vapour in our atmosphere; and hence we have a regular hollow shell of magnetic matter enveloping the earth, and capable, when magnetism is induced upon it by an exterior cause, of producing all the phenomena of terrestrial magnetism. In its undisturbed state of equilibrium, this magnetic atmosphere will act upon the needle, according to the laws which Mr Barlow found to regulate the action of an iron sphere or shell; but these laws will be modified by those which regulate the thermal state of the globe, and will be disturbed by sudden changes of temperature, and by the various electrical agencies which exercise so powerful an influence over the meteorological condition of the atmosphere. The more violent disturbances of electrical equilibrium will fuse, and throw down, in the form of meteoric stones, the metallic vapour in their vicinity. Inferior electrical actions will render their progress visible in the form of lightning and fiery meteors, arising from the heated state of the metallic particles; while still feebler electricities will, by their accompanying heat, produce the sheets of summer lightning, and the more continued and shifting phenomena of the aurora. Hence the electric sounds and other accompaniments of the aurora; hence its connection with the magnetic pole and equator; and hence the disturbance of the needle, or the *magnetic hurricanes*, as Humboldt calls them, while the regular action of the metallic atmosphere is disturbed during the prevalence of the aurora, or of thunder-storms. These views receive some support from the observations of MM. Gay-Lussac and Biot, from which it appears that the intensity of terrestrial magnetism is not diminished at the height of 13,000 feet above the earth; and Mr Henwood found the magnetic intensity as strong 710 feet above the level of the sea as at the bottom of a mine 950 feet below the same level. Kupffer, on the authority, we believe, of a single observation, has given an opposite opinion; and Saussure conceived that the intensity was less on the Col de Geant than at Geneva, but the numbers which he gives actually authorizes the opposite conclusion.

Effect of height on the intensity.

From a series of observations made in July 1830 by M. Quetelet, in Switzerland, it appears that in place of the intensity diminishing with the height, it actually increases, the increase taking place gradually (with the exception of Bonneville) in ascending from Geneva to the Col de Balme, as is shown in the following table:[1]—

	Horizontal Intensity.		Horizontal Intensity.
Geneva	1·0805	Chamouni	1·0935
Bonneville	1·0765	Col de Balme	1·0917
Sallenches	1·0815	Martigny	1·0921
St Gervais	1·0861	Hospice St Bernard	1·0966
Vaudagnes	1·0884	Simplon Village	1·0987
Servoz	1·0872	Domodossolo	1·0997
Mer de Glace	1·0885		

An argument for the atmospheric origin of terrestrial magnetism may be derived from the admitted fact, that *there actually exists in our atmosphere a powerful source of magnetism*, with which the south pole of the needle has a distinct connection. This source of magnetism is the *aurora borealis*, and the south pole of the dipping needle points to the focus to which the beams of the aurora converge. These beams act as magnets, as we have seen in a previous section; the action of our magnetic atmosphere, when undisturbed by any other cause but that of temperature, tends to fix the needle in a specific direction, which varies within certain limits, depending on the ordinary changes of temperature; but when the regular magnetism of the atmosphere is disturbed by electric or other causes, the needle must necessarily be affected by the displacement or altered temperature of the magnetic matter, as exhibited in the motions and variations in the lustre of the beams of the aurora. The magnetic pole, therefore, in our hemisphere, will be a north pole attracting the south end of the needle, and creating an elevation of the south end in place of a dip of the north end.

By the aid of these views, all the magnetic phenomena of the aurora borealis, so ably described by Dr Dalton, and the disturbances of the needle, so accurately observed by M. Arago, in reference to the auroræ that occurred in every part of the northern hemisphere, may be satisfactorily explained, as we have attempted to do in a preceding section.

Magnetic influence of the sun.

In seeking for a cause which is capable of inducing magnetism on the ferruginous matter of our globe, whether we place it within the earth or in its atmosphere, we are limited to the SUN, to which all the magnetic phenomena have a distinct reference; but whether it acts by its heat or by its light, or by specific rays, or influences of a magnetic nature, must be left to future inquiry. Without placing any reliance on the observations which have been supposed to indicate a magnetic action in the violet rays, we attach some importance to the observations of Barlocci and Zantedeschi, who found that both natural and artificial magnets had their magnetism greatly increased by exposure to the common solar rays; a result which could not arise from their heating power, as an increase of temperature invariably diminishes the power of magnets.

Dalton's views respecting the aurora.

In the work of Dr Dalton, published in 1793, to which we have already referred, there are several ingenious hypothetical views respecting the cause of the aurora borealis and its magnetic influence, with which we were not acquainted till the sections on that subject were written; but as these views strongly confirm the hypothesis of terrestrial magnetism which we have ventured to bring forward, we shall state as briefly as we can the leading ideas of Dr Dalton.

1. *The region of the aurora* is 150 miles above the earth's surface. Immediately above the earth's surface is the region of the clouds, then the region of meteors called falling stars and fire-balls, and beyond this region is that of the aurora. In proof of the great height of the aurora (independent of actual measurement) Dr Dalton adduces its extreme attenuated light, which, he says, may spread over one-half of the hemisphere, and not yield more light than the full moon. "This," he continues, "arises from the extreme rarefaction of the air, which is almost tantamount to a Toricellian vacuum; in fact, the light of the aurora exactly corresponds with that of the electric spark, when sent through a tube in which the air has been rarefied to as high a degree as can be effected by a good air-pump."

2. *The matter of the aurora.*—"From the conclusions in the preceding section," says Dr Dalton, "we are under the necessity of considering the *beams* of the *aurora borealis* of a *ferruginous* nature, because nothing else is known to

---

[1] These results are not consistent with those obtained by Gay-Lussac and Biot, and by others, as mentioned in the history prefixed to this article. The careful experiments of Prof. J. D. Forbes, made on the Alps and Pyrenees, with Hansteen's intensity needles, resulted in giving a negative co-efficient to the height; and when eliminated by the method of least squares, the probable co-efficients of varied intensity for 100 feet of elevation were as follows:—

Alps, with the cylindrical needle	·000033 of the absolute intensity.
Do. flat needle	·000027
Pyrenees, with both	·000053
Probable mean	·000034

Hence, to produce a variation of ·001, an elevation of 3000 feet is necessary.

be magnetic; and consequently that there exists in the higher region of the atmosphere an electric fluid, partaking of the properties of *iron*, or rather of *magnetic steel;* and that this fluid, doubtless from its magnetic property, assumes the form of cylindric beams." "My *fluid of magnetic matter*," adds Dr Dalton in another place, "is, like magnetic steel, a substance possessed of the properties of magnetism." "Whether any of the various kinds of air or elastic vapour we are acquainted with is magnetic, I know not, but hope philosophers will avail themselves of these hints to make a trial of them."

3. *Exciting cause of the magnetism of the aurora.*—"With regard to the exciting cause of the aurora, I believe it will be found in change of temperature." "Nothing is known to affect the magnetism of steel; heat weakens or destroys it; electricity does more—it sometimes changes the pole of one denomination to that of another, or inverts the magnetism. Hence we are obliged to have recourse to one of these two agents, in accounting for the mutations above mentioned. As for heat, we should find it difficult, I believe, to assign a reason for such sudden and irregular productions of it in the higher regions of the atmosphere, without introducing electricity as an agent in these productions; but rather than make such a supposition, it would be more philosophical to suppose electricity to produce the effect on the magnetic matter *immediately.* "The beams of the *aurora* being magnetic, will have their magnetism weakened, destroyed, or inverted, *pro tempore*, by the several electric shocks they receive during an aurora."

4. *The nature of the magnetism of the beams of the aurora.*—Dr Dalton conceives the magnetism to be permanent, and not induced; and *each beam to be as it were a separate magnet*, with the regular polarity of permanent magnets. "I conceive that a beam may have its magnetism inverted, and exist so for a time, &c. . . . and I farther conceive, that when the beam is restored to its natural position of the north pole downward, it is effected, not by inverting the beam wholly as a beam (for this is never observed in an aurora), but by inverting the constituent particles, which may easily be admitted, of a fluid."

"If a magnet be required to be made of a given quantity of steel, it is found by experience to answer best when the length is to the breadth as 10 to 1 nearly. It is a remarkable circumstance, that the length and breadth of the magnetic beams of the aurora should be so nearly in that ratio. Query, if a fluid mass of magnetic matter, whether elastic or inelastic, were swimming in another fluid of equal density, and acted on by another magnet at a distance, what form would the magnetic matter assume? Is it not probable it would be that of a cylinder, of proportional dimensions to the beams of the *aurora?*

5. *Governing cause of the magnetism of the aurora.*—"As the beams," says Dr Dalton, "are swimming in a fluid of equal density with themselves, they are in the same predicament as a magnetic bar or needle swimming in a fluid of the same specific gravity with itself; but this last will only rest in *equilibrio* when in the direction of the *dipping needle*, owing to what is called the *earth's magnetism;* and as the former also rests in that position only, the effects being similar, we must, by the rules of philosophizing, ascribe them to the same cause. Hence then it follows, that THE AURORA BOREALIS IS A MAGNETIC PHENOMENON, AND ITS BEAMS ARE GOVERNED BY THE EARTH'S MAGNETISM." "I am aware that an objection may be stated to this; if the beams be swimming in a fluid of equal density, it will be said they ought to be drawn down by the action of the earth's magnetism. Upon this I may observe, that it is not my business to show why this is not the case, because I propose the magnetism of the beams as a thing demonstrable, and not as a hypothesis. We are not to deny the cause of gravity because we cannot show how the effect is produced. May I not the difficulty be lessened by supposing the beams of less density than the surrounding fluid?"

Although this brief abstract of Dr Dalton's essay contains many views which in their general bearing add to the probability of the hypothesis which we have maintained, yet we must state in a few words the difference between the two hypotheses.

1. According to our views, terrestrial magnetism resides wholly in the earth's atmosphere, which contains throughout its whole extent ferruginous and other metallic matter, and sulphureous exhalations, all of which are carried off by evaporation, by ejection from volcanoes, and by the returning strokes of electricity from the earth to the air. The actual existence of such materials in the atmosphere, particularly sulphureous and ferruginous matter, is proved by the observations of Fusinieri, and by the existence of meteoric stones and other solid substances which fall on the earth.

2. The magnetism which directs the needle is induced upon the magnetic matter in the atmosphere, like that of an iron sphere, by some exterior cause, although it is very probable that small local effects may be produced by ferruginous matter within the earth, and near its surface; but the only effect of these will be to produce small irregularities in the intensity of the magnetism of the needle, and in its direction.

3. As the colour of the electric spark, when taken from different bodies, or when passing through different media, depends on the solid matter which it renders luminous, so the different colours of lightning, of the auroral beams, of falling stars, and of meteors of every kind, are produced by the heat of the electric fluid either rendering the material substance visible by incandescence, or throwing it into a state of combustion.

4. The beams of the aurora are those portions of the magnetic atmosphere through which electricity is passing, and which, by being heated to different degrees are brought to different states of incandescence, and have their induced magnetism increased, like that of all ferruginous bodies which are brought to a temperature less than that of white heat.

Views of Mr Grover,

In his work *On the Magnetic Orbit*, already referred to, Mr Grover has expressed some new opinions on the nature and locality of terrestrial magnetism. He considers the atmosphere as its immediate source, containing within it isolated columns of conducting media, which surround the earth in such a manner, that in 365 revolutions the sun generates in it an electro-magnetic circulation. The earth's surface then becomes enveloped in a vast electro-magnetic spiral coil, and its inhabitants are thus placed between the coil and the surface by those peculiar motions of the earth which arise from the yearly cycle finding its period at different hours of the day, and on different meridians. Such a change may take place, from time to time, in the precise position of this great atmospheric coil as would correspond with the orbit of the magnetic revolution.

and of Sir W. Harris.

In reference to these views Sir W. Harris remarks, "that the phenomena of periodical variations depend evidently on the action of heat and the position of the sun, and probably in resulting thermo-magnetic currents. Beyond this mere assumption, however, we have no very secure basis for reasoning. The most admissible view, however, of this kind of action, is the following:—During the daily motion of the earth, its surface, especially about the tropics, is successively heated and cooled in successive points, and in an E. and W. direction. Then if we admit that thermo-magnetic currents are thus excited (as in Dr Seebeck's experiment of heating a combination of antimony and bismuth bars at one point, and cooling them at another), and that they circulate in an E. and W. direction over the earth's surface, the result will be a magnetic development in a N.

and S. direction, and hence there will be a magnetic development in a direction nearly parallel with its axis."[1]

The opinion that magnetism resides wholly or to a great extent in our atmosphere, has been rendered more probable by the important discovery of Dr Faraday, that oxygen gas, which composes two-ninths of the atmosphere by weight, is magnetic like iron, while nitrogen has no such property. Hence it is to the magnetic constitution and condition of the atmosphere, and the changes effected in it by variations of temperature and pressure, winds, currents, rain and snow, &c., that Dr Faraday refers the annual and diurnal variation of the needle.

Although it is universally admitted that a source of magnetism has been proved to exist in our atmosphere, and though it is evident that the force which emanates from it is greater than any magnetic force which can be proved to have its origin in the solid part of the earth, yet it may be asked if there is any reason for believing that the magnetism in the atmosphere is strong enough to be considered as the only source of terrestrial magnetism? To this question, some of the facts already stated afford a pretty satisfactory answer. M. Arago showed that the auroræ which exist only at St Petersburg, in Siberia, and even in North America, actually disturb the magnetic needle at Paris; and he considered it highly probable that the auroræ even round the south pole of our globe extend their influence to Paris. If a force of such magnitude exists in insulated beams which form regular magnets, according to Dr Dalton, we need not scruple to suppose that a ferruginous atmosphere is capable of producing that degree of intensity which characterizes terrestrial magnetism, and that the disturbances exhibited at Paris on the magnetic needle are the effect of local diminutions or augmentations of the magnetic force in Siberia, America, or even in the southern hemisphere.

CHAP. X.—ACCOUNT OF THE DIFFERENT METHODS OF MAKING ARTIFICIAL MAGNETS.

Methods of making artificial magnets.

In the "History of Magnetism" we have already made a brief reference to the principal methods of making artificial magnets. We shall now proceed to give a short account of the methods themselves.

In the infancy of the science, a bar B of hard steel was magnetized by rubbing it throughout its whole length on one of the poles N of a natural or artificial magnet A, in a direction at right angles to the line joining the two poles of the primitive magnet. By this process the new bar *a* will be rendered slightly magnetic, but its magnetism cannot possibly be completely developed unless in the two cases where the new bar is extremely small, or the primitive magnet A extremely powerful; and the magnetism which is communicated often exhibits different poles, or consequent points as they are called, throughout the length of the new bar.

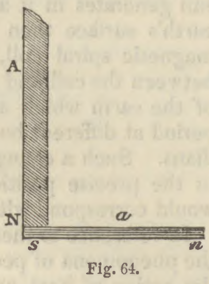

Fig. 64.

In using this method, the exciting pole should be slightly pressed upon the new bar; and after reaching the end of the bar at *s*, it must be lifted up and applied again to the other end, the friction being always made in the same direction.

Another old method of making magnets consisted in placing the end *s* of a new bar B *in contact* merely with one of the poles N of a powerful magnet, and striking the new bar so as to make it ring during the time of its application. This method, however, like the first, will be effectual only for very small bars; the pole *s* will be the strongest, and the neutral point at B will be nearer *s* than *n*.

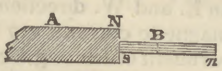

Fig. 65.

A more efficacious method of magnetizing small bars by simple contact is shown in the annexed figure, by placing the new bar B between the opposite poles N, S of two strong magnetic bars A, A', of nearly equal power. In this case the magnetism of B will be nearly twice as great as when only one, A or A', is used; and if there are no consecutive poles produced the neutral point B will bisect *ns*.

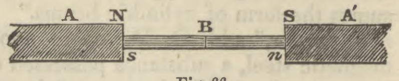

Fig. 66.

These simple methods were discontinued when the principles of magnetic induction were better understood, and several ingenious and highly effective processes of making artificial magnets were invented by the philosophers of the eighteenth century. The first of these was that of Mr Knight.

SECT. I.—*Account of Dr Gowin Knight's method of making Artificial Magnets.*

Knight's method.

Dr Gowin Knight, a physician in London, was long celebrated for the excellence of the artificial magnets which he made, and some of which he presented to the Royal Society. The method which he used was kept a secret during his life, but was published after his death by Mr Wilson.

The bar or needle B, which he intended to magnetize, was tempered at a *cherry-red heat*, and placed under the opposite poles N, S of two equal magnets. These magnets are then separated in opposite directions SA', NA, so that the south pole S of the one passes over the *north-polar* half B*n* of the bar B, and the north pole N of the other, over the *south-polar* half B*s* of B. This operation is repeated several times, till the magnetism of the bar B is fully developed.

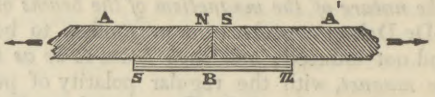

Fig. 67.

In this process the north pole N, while it attracts to the half B*n* all the south-polar magnetism in B*s*, repels at the same time into B*s* all the north-polar magnetism of B*n*. The same is true, *mutatis mutandis*, with the south pole S. When the bars A, A' are large and powerful, it has been found that this process is capable of communicating to small bars all the magnetism of which they are susceptible. (See *Phil. Trans.*, vol. xliv., 1746–47).

By this process Dr Knight constructed a magnetic machine of great power, with the view of developing in steel

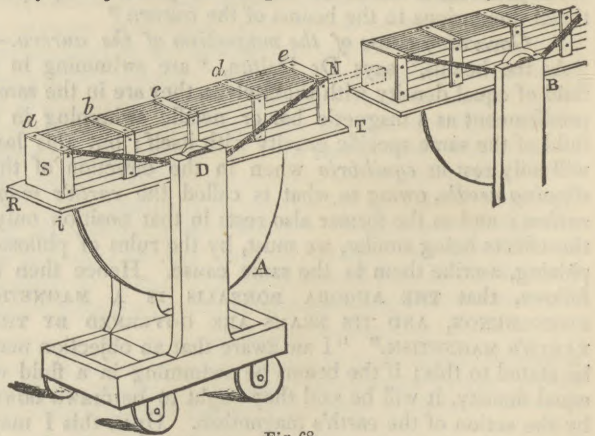

Fig. 68.

---

[1] *Rudim. Mag.* iii. 119.

needles a very intense degree of magnetism. This machine consisted of 480 bar-magnets, each 15 inches long, 1 inch wide, and half an inch thick, arranged in two separate magazines, having 240 magnets in each; one of these magazines is represented in the annexed figure at SN. The bars were arranged in four lengths *ab*, *bc*, *cd*, and *de*, having their north poles turned the same way, and consequently their dissimilar poles in contact. Each bundle *ab* contained 60 bars, arranged in six beds of 10 bars each, set edgewise, so that there were 10 bars in width and 6 in depth. Each magazine weighed 500 lb., and was mounted on rollers as in the figure. Dr Robison saw this machine about the year 1800, and described the effect of pressing together the dissimilar poles of the two magazines as if one were pressing against a feather bed. Dr Faraday examined them in 1830. Upon placing a cylinder of soft iron 1 foot long and $\frac{3}{4}$ths of an inch in diameter across the dissimilar poles, a force of 100 lb. was necessary to overcome the attractive force.

SECT. II.—*Account of Duhamel's method of making Artificial Magnets.*

Duhamel's method.

After Dr Knight's process had been known and used, the artificial magnets which were made by it were in great request, and distributed throughout Europe. When the process, however, was applied to bars of great size, it was found to be defective; and M. Duhamel of the Academy of Sciences, in conjunction with M. Antheaume, set themselves to devise a better method, which is represented in the annexed figure. The bars B, B′ to be magnetized are placed parallel to each other, and have their extremities united by two pieces M, *m* of soft iron, at right angles to the bars. He then took two strong magnets A, A′, or two bundles of small bar-magnets, the bars of each bundle having their similar poles together; and having placed them, as in the figure, at an angle of about 90°, or inclined 45° to the bar B, they were separated from each other, as already described in the explanation of figure 67. The same operation was repeated on the other bar B′, and continued alternately on both till the magnetism was supposed to be completely developed in both bars. When A and A′ are placed upon the second bar B′, the disposition of the poles must be reversed, the pole that was formerly to the right hand being now placed to the left. The two bars B, B′ are then turned, so that the undermost faces are uppermost, and the same process carried on as before.

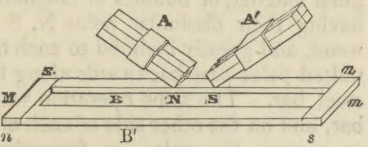

Fig. 69.

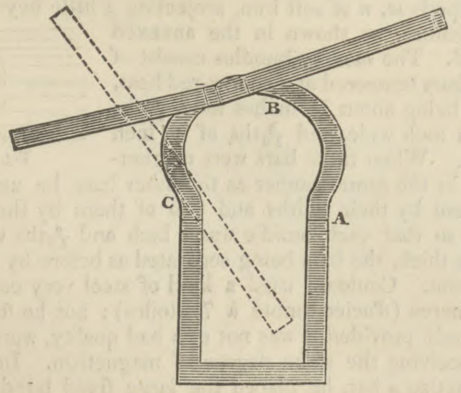

Fig. 70.

The distinctive peculiarity of Duhamel's process consists in the employment of the pieces of iron M, *m*, and in the use of bundles of small bars, which are more efficacious than two single ones of the same size.

The very same method is applicable to curved bars, or those of the horse-shoe form, as shown in fig. 70, where the inclined bars are carried round the curved bar ABC, exactly as they were along the straight bar B.

SECT. III.—*Account of Mr Michell's method of making Artificial Magnets.*

Michell's method of double touch. A.D. 1750.

About the same time that Duhamel was occupied with this subject, Mr Michell of Cambridge, and Mr Canton, were separately engaged in the same inquiry. Mr Michell published his method in 1750, to which he gave the name of the *method of double touch*. Having joined together, at the distance of a quarter of an inch, two bundles of strongly magnetized bars A, A′ (fig. 71), their opposite poles N, S being together, he placed five or more equal steel bars B, B′, B′, B″, B″ in the same straight line; and resting the extremity of the bundle of magnets A, A′ upon the middle of the central bar B, he moved them *backwards* and *forwards* throughout the whole length of the line of bars, repeating the operation on each side of the bars, till the greatest possible effect was produced. By this method Mr Michell found that the middle steel bars B, B′, B′, acquired a very high degree of magnetic virtue, and greater than the outer bars B″, B″; but by placing these last bars in the middle of the series, and repeating the operation, they acquired the same degree of magnetism as the rest.

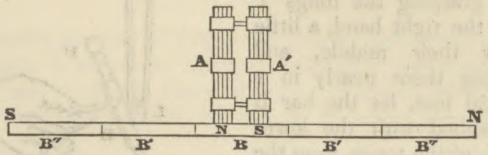

Fig. 71.

Mr Michell states, that two magnets will, by his process of double touch, communicate as strong a magnetic virtue to a steel bar, as a single magnet of five times the strength, when used in the process of single touch. The bars A, A′ act with the sum of their powers in developing magnetism in all parts of the line of bars between them, and with the difference of their powers in all parts of the line of bars beyond them. The external bars act the same part in this process as the two pieces of soft iron in the method of Duhamel.

SECT. IV.—*Account of Canton's method of making Artificial Magnets.*

Canton's method.

In the year 1751 Mr Canton published his process, which he regarded as superior to preceding ones. He placed the bars as in Duhamel's method, joined by pieces of soft iron. He then applied Michell's method of double touch, and afterwards he separated the two bundles of magnets A, A′, and having inclined them to each other, as in Duhamel's method, he made them rub upon the bar from the middle to its extremities. The peculiarity of Canton's method is the union of these two processes; but Coulomb and others have regarded the latter part of the process as the only effectual one.

Without natural or artificial magnets.

In order to make artificial magnets without the aid either of natural loadstones or artifical magnets, Mr Canton gives the following detailed process:—

He takes six bars of soft and six of hard steel, the former being smaller than the latter. The bars of *soft* steel should be 3 inches long, $\frac{1}{4}$th of an inch broad, and $\frac{1}{20}$th thick; and two pieces of iron must be provided, each having half the length of one of the bars, and the same

Methods of making Artificial Magnets.

breadth and thickness. The bars of *hard* steel should be each 5½ inches long, ½ inch broad, and $\frac{3}{20}$ths of an inch thick, with two pieces of iron of half the length, and the same breadth and thickness.

All the bars being marked with a line quite round them at one end, take an iron poker and tongs, or two bars of iron, the larger and the older the better, and fixing the poker P upright, as in fig. 72, hold to it with the left hand, near the top P, by a silk thread, one of the *soft* bars B, having its marked end downwards; then grasping the tongs T with the right hand, a little below their middle, and keeping them nearly in a vertical line, let the bar B be rubbed with the lower end L of the tongs, from the marked end of the bar to its upper end, about ten times on each side of it. By this means the bar B will receive as much magnetism as will enable it to lift a small key at the marked end; and this end of the bar being suspended by its middle, or made to rest on a point, will turn to the *north*, and is called its *north* pole, the unmarked end being the *south* pole.

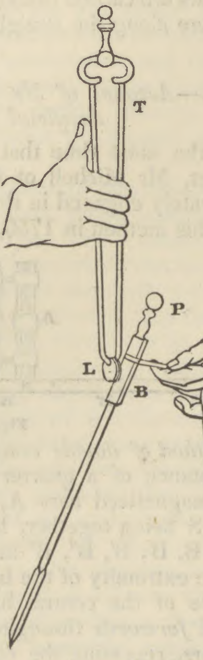

Fig. 72.

When four of the soft-steel bars are thus rendered magnetic, the other two AC, BD (fig. 73), must be laid parallel to each other, at the distance of about ¼th of an inch, as in the figure, having their dissimilar poles united with the smallest pieces of iron AB, CD. Two of the magnetized bars are then to be placed together, as at G, with their similar poles united, and the other two as at K; and when separated by a piece of wood I, they are slid four or five times backwards and forwards along the whole length of the bar AC, so that the marked end F of G is nearest the unmarked end of AC, and *vice versa*. This operation is carefully repeated on BD, and on the other sides of both AC and BD. When this is done, the bars AC, BD are to be taken up and substituted for the two outer bars of the bundles G, K, these last being laid down in the place of the former, and magnetized in a similar manner. This operation must be repeated till each pair of the soft bars has been magnetized *three* or *four* times.

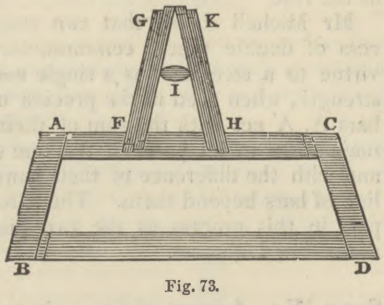

Fig. 73.

When the six soft bars are thus magnetized, they must be formed into two bundles of three each, with their similar poles together, and must be used to magnetize two of the *hard* bars in the manner already described; and when they are magnetized, other two of the hard bars must be touched in a similar manner. The soft bars are now to be laid aside, and the remaining two hard bars magnetized by the *four* hard bars already rendered magnetic; and when this is done, the operation should be repeated by interchanging the hard bars, till they are impregnated with the greatest degree of permanent magnetism which this method is capable of communicating to them.

Methods of making Artificial Magnets.

In performing the above operations, which may be completed in about half an hour, the bars AC, BD, and the pieces AB, CD should be placed in grooves, or fixed between pins of wood or brass, to keep them steady during the successive frictions which are applied to them. According to Canton, each of the six artificial magnets thus made will lift about 28 ounces troy. They should be kept in a wooden box, and placed as in the annexed figure, so that no two poles of the same name may be together, and the pieces of iron AB, CD (fig. 74) placed beside them.

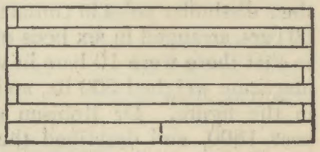

Fig. 74.

SECT. V.—*Account of Æpinus's method of making Artificial Magnets.*

Æpinus's method.

The method of magnetizing steel bars by the double touch was greatly improved by Æpinus. In place of the pieces of iron M, *m*, used by Duhamel, he used magnets, and formed the rectangle with the two steel bars to be magnetized, having their extremities united by two magnets M, *m*, placed as in figure 69. He then placed the original magnet, or bundles of magnets A, A′, as in the figure, having their dissimilar poles N, S separated by a piece of wood, and greatly inclined to each other; and he made the united poles pass backwards along the whole length of the steel bar. The same operation was repeated on the other bar, and on the other side of each of them, care being taken to reverse the poles, as formerly mentioned, when the rubbing bars are removed from the one steel bar to the other. Æpinus found that a maximum effect was produced when the bars A, A′ were inclined 20° or 30° to the steel bar over which they passed.

SECT. VI.—*Account of Coulomb's method of making Artificial Magnets.*

Coulomb's method.

The method of making artificial magnets employed by Coulomb consists of the most efficacious parts of the preceding processes, improved and extended by long experience in the art. The apparatus which he uses consists of *fixed* and *moving* bundles of magnets. Each of the fixed bundles consists of *ten* bars of steel tempered at a cherry-red heat, their length being about 21 inches, their breadth $\frac{6}{10}$ths of an inch, and their thickness ⅛th of an inch. Having rendered them as strongly magnetic as possible, with a natural or an artificial magnet, he joined them with their similar poles together, and formed them into two beds of four bars each, these beds being separated by small rectangular parallelopipeds *m*, *n* of soft iron, projecting a little beyond their extremities, as shown in the annexed fig. 75. The *moving* bundles consist of four bars tempered at a cherry-red heat, each being about 16 inches long, $\frac{6}{10}$ths of an inch wide, and $\frac{2}{10}$ths of an inch thick. When these bars were magnetized in the same manner as the other bars, he united two of them by their widths and two of them by their thickness, so that each bundle was 1 inch and $\frac{2}{10}$ths wide, and $\frac{4}{10}$ths thick, the bars being separated as before by pieces of soft iron. Coulomb used a kind of steel very common in commerce (d'acier timbré à 7 etoiles); but he found that all kinds, provided it was not of a bad quality, were capable of receiving the same degree of magnetism. In order to magnetize a bar, he placed the large fixed bundles M, N in the same straight line, and at a distance a little less than the length of the bar to be magnetized; and this bar BB′

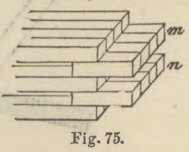

Fig. 75.

Methods of making Artificial Magnets.

was placed, as in fig. 76, so as to rest on the projecting pieces of iron, so that the contact took place only over a length of $\frac{1}{6}$th of an inch; the two moving bundles A, A′ having their dissimilar poles separated by a small piece of wood or copper about $\frac{1}{5}$th of an inch wide between them, and each being inclined at an angle of 20° or 30° to the bar BB′. The united poles of the moving bundles are then moved successively from the centre to each extremity of the bar BB′, so that the number of frictions upon each half of the bar may be equal. When the last friction has been given, the united poles are brought to the middle point of the bar BB′, and then withdrawn perpendicularly. The same operation is then repeated on the other side of the bar BB′. If we wish to employ the method of Duhamel in place of that of Æpinus, we do not require the piece of wood or copper, but have only to separate the bars when their united poles are in the middle of the bar BB′, making each pole pass to the extremity of it.

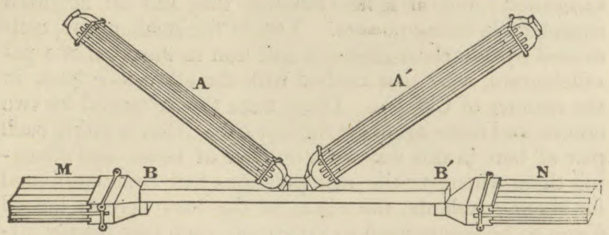

Fig. 76.

When the fixed and moving bundles are composed of bars which have not been magnetized to saturation, we must form new bundles with the newly magnetized bars, whose magnetism will be stronger than those by which they were magnetized, and by their means magnetize anew the bars first used; and by repeating this process three or four times, the bars may be raised to the highest degree of magnetic virtue.

When the bars BB′ to be magnetized are very large, the moveable bundle should contain more than four bars, each of the bars retreating about half an inch in the direction of their thickness, as shown in the annexed figure. The advantage of this displacement arises from the fact, that the highest degree of magnetism resides in the extremity of the bar. Hence, by this arrangement, not only the most efficacious parts of the moving bar are brought into contact with the bar to be magnetized, and act more powerfully, but the bar nearest to the central one in the bundle tends not merely to maintain, but to augment, in its extremity, its degree of magnetism. The third bar produces the same good effect upon the second, and so on with the rest.

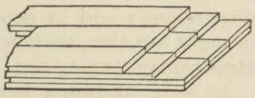

Fig. 77.

SECT. VII.—*Account of M. Biot's method of making Artificial Magnets.*

Biot's method.

M. Biot proposed several important improvements on the process of Coulomb. As the bars are always bent a little in tempering, he recommends that they should at first be brought to as hard a temper as possible, and then annealed to the first shade of yellow. By this means they will have a sufficient degree of malleability to be again brought into shape, while they possess sufficient coercive power for receiving and retaining a high degree of magnetism. Regarding it as of essential importance to insure an intimate contact between the plates of the large bundles and the soft iron or armour by which they are united, Biot formed his armour of several plates of very soft iron, which cover the elementary plates at that part of their extremities where the repartition of free magnetism is perceptible. These plates of soft iron form part of a mass of the same nature terminating in the form of a trapezoid, as shown in the annexed figure, and the plates of steel are inserted in it, as shown by the dotted lines; so that the plates which lie in the axis of the bundles project a little beyond the lateral plates. The whole is then bound together with a collet of soft iron, held firmly by a screw. Biot remarked, that he has found from experience that this arrangement, indicated by theoretical considerations, is extremely advantageous.

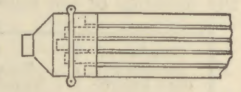

Fig. 78.

Methods of making Artificial Magnets.

Coulomb's method of arming magnets.

Coulomb's method of fitting up, arming, and preserving his magnets is shown in the annexed figure, representing two artificial magnets, armed at their extremities with two iron parallelopipeds, N, S, N′, S′; N, N′ being the north poles, and S, S′ the south poles. These parallelopipeds have their inner ends enveloped within the magnetic bars. The opposite poles N, S′, N′, S, are joined by pieces of soft iron, A, B, and the bars of each magnet are held together by the upper bands *a*, *b*, *a*′, *b*′.

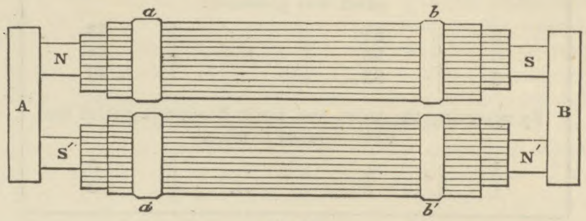

Fig. 79.

With an apparatus of this kind, each part weighing 15 or 20 pounds, 80 or 100 pounds is required to separate the pieces A, B from the poles, and an ordinary needle is magnetized to saturation by merely placing it upon the ends N, S′ or N′, S.

SECT. VIII.—*Account of Dr Scoresby's method of making Artificial Magnets.*

Scoresby's method.

A very simple and efficacious method of making artificial magnets by percussion was published by Dr Scoresby.[1] That iron became magnetic when struck by successive blows of a hammer in the direction of the dipping needle, was known to Dr Gilbert, and also to M. Du Faye and Dr Desaguliers;[2] but it is to Dr Scoresby that we owe a complete investigation of the subject. In order to determine the effects produced by percussion, Dr Scoresby used two methods, the one by observing the weight which the new magnet lifted, and the other by measuring the deviation which it produced on a magnetic needle. The following experiments were made with a cylindrical bar of soft steel $6\frac{1}{2}$ inches long, $\frac{1}{4}$th of an inch in diameter, and weighing 592 grains. It was placed in a vertical position, resting on a piece of tin, and struck with a hammer of 12 ounces.

Number of Strokes at each Experiment.	Total Number.	Weight suspended by the Bar.	Deviation of the Needle; distance of Needle, three inches.
1	1	2 grs.	8°
1	2	0	10
5	7	4	12
10	17	6½	12½
5	22	6½	12½

When the steel bar was placed upon a stone, the effect

---

[2] *Phil. Trans.*, 1738.

Methods of making Artificial Magnets.

was the same; but, as the following experiments show, a great increase of power was obtained by supporting the lower end of the bar upon the upper end of a large bar of iron or soft steel. The hammer weighed 12 ounces, and the distance of the needle was 3 inches.

Number of Strokes at each Experiment.	Total Number.	Weight suspended by the Bar.	Deviation of the Needle.
1	1	6½ grs.	13°
1	2	14	16
1	3	...	18
4	7	37	21
5	12	45	25
10	22	88	27
20	42	88	30
30	72	...	31
10	82	...	31½
By using a hammer weighing 22 ounces, an increased effect was produced.			
3	85	...	33
5	90	130	34
3	93	...	30
By reversing the poles, and again hammering with the twelve-ounce hammer.			
1	...	...	5
1	2	...	2

From these experiments it follows, that a cylindrical bar of soft steel, weighing 592 grains, can be made to lift only 6½ grains, when struck in a vertical position, with its lower end resting upon tin or stone; whereas the same bar, when struck with twenty-two blows upon a rod of iron suspended at its lower end, which was a north pole, lifted 88 grains; by using a larger hammer, its lifting power increased to 130. When the steel bar was reversed, so that its south pole was uppermost, its magnetism was almost destroyed by a single blow, and two blows were sufficient to change its poles. Dr Scoresby found that when the steel magnet was struck in the plane of the magnetic equator, its polarity also disappeared; but several blows were necessary to effect this change.

In another set of experiments on the effect of percussion on magnets, he employed a flat bar-magnet $7\frac{7}{10}$th inches long, ½ inch wide, $\frac{1}{7}$th thick, and weighing 1170 grains.

When suspended vertically, with its south end uppermost, it produced, at the distance of 8 inches, a deviation of 45° on the needle; but after sixty, eighty, and a hundred blows, the deviation was reduced to 25°.

When the north pole was placed uppermost, other thirty blows reduced the deviation still farther, from 25° to 14°.

When the bar was again magnetized, and hammered upon a piece of tin, it produced a deviation of 50°; but after twenty blows, with the south pole uppermost, the deviation became 33°. By other sixty blows, with the north pole uppermost, the deviation became 24°.

From the results obtained in the preceding experiments, Dr Scoresby deduced the following method of making artificial magnets by percussion:—

"I procured two bars of soft steel 30 inches long and 1 inch broad, also six other flat bars of soft steel 8 inches long and ½ inch broad, and a large bar of soft iron. The large steel and iron bars were not, however, absolutely necessary, as common pokers answer the purpose very well; but I was desirous to accelerate the process by the use of substances capable of aiding the development of the magnetical properties in steel. The large iron bar was first hammered in a vertical position; it was then laid on the ground with its acquired south pole towards the south, and upon this end of it the large steel bars were rested while they were hammered; they were also hammered upon each other. On the summit of one of the large steel bars, each of the small bars, held also vertically, was hammered in succession; and in a few minutes they had all acquired considerable lifting powers. Two of the smaller bars, connected by two short pieces of soft iron in the form of a parallelogram, were now rubbed with the other four bars, in the manner of Canton. These were then changed for two others, and these again for the last two. After treating each pair of bars in this way for a number of times, and changing them whenever the manipulations had been continued for about a minute, the whole of the bars were at length found to be magnetized to saturation, each pair readily lifting above 8 ounces.

Methods of making Artificial Magnets.

"In accomplishing this object, I took particular care that no magnetic substance was used in the process. All the bars were freed of magnetism before the experiment, so that none of them, not even the largest, produced a deviation of five degrees on the compass at 3 inches distance. Any bars which had been strongly magnetized, and had had their magnetism destroyed or neutralized (either by hammering, heating, or by the simultaneous contact of the two poles of another magnet placed transversely), I always found had a much greater facility for receiving polarity in the same direction as before, than the contrary. Hence it generally happened that one blow with the original north end downwards, produced as much effect as two or three blows did with the original south end downwards."

By this ingenious process, any person who has no magnets within his reach may communicate the strongest degree of permanent magnetism to hard steel bars of any magnitude, the bars magnetized by percussion being employed, as in the process of Coulomb, to magnetize the large bars which are required.

Sect. IX.—*Method of making Horse-Shoe Magnets.*

Method of making horse-shoe magnets.

Horse-shoe magnets are those which have the form of a horse-shoe, as shown in fig. 70; and this form is, generally speaking, the most convenient for use, and for the preservation of their magnetic power. In all experiments where a large weight is to be lifted, the horse-shoe magnet is indispensable; and in consequence of the two poles being brought together, they may be substituted with great advantage for magnetizing steel bars by the method of double touch.

In order to form a powerful magnetic battery, the best way is to unite a number of similar horse-shoe magnets, with their similar poles together, and to fix them firmly together in a case of copper or leather. The following is the method recommended and used by Professor Barlow:—

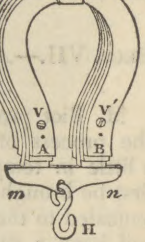

Fig. 80.

He took bars of steel 12 inches long, and having bent them into the horse-shoe shape, their length was 6 inches, their breadth 1 inch at the curved part, and ¾ths of an inch at their extremities, and their thickness ¼th of an inch. They were filed very nicely, so as to correspond, and lie flatly upon each other. They were then drilled with three holes in each, as seen in the figure, and by means of screws V, V' passing through these holes, *nine* horse-shoe bars were bound together. When the heads and ends of the screws were constructed so as to leave the outer surfaces smooth, the mass of bars was filed as if they were one piece, and the surface made flat and smooth. When the bars were separated, they were carefully hardened, so as not to warp, and when they had been well cleaned and rendered bright, but not polished, they were magnetized separately in the following manner:—When the two extremities of the bar are connected by a piece of soft iron M (fig. 81), the magnetism may be developed in the two

Methods of making Artificial Magnets.

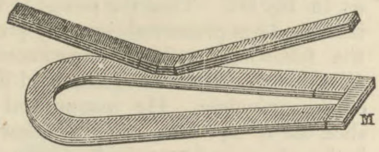

Fig. 81.

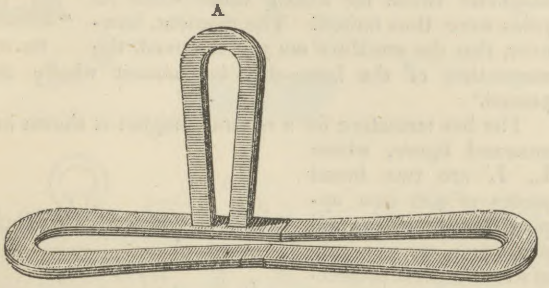

Fig. 82.

halves by Duhamel's method, as in fig. 81; or, following Æpinus, we may apply a strong magnet to each pole, and connect their extremities either with a piece of soft iron or another magnet; or we may apply two horse-shoe magnets to each other, as in fig. 82, uniting the poles which are to be of contrary names. When the magnet or magnets are prepared in any of these ways, they are then to be magnetized with another horse-shoe magnet A, by placing its north pole next to what is to be the south pole of one of the horse-shoe bars, and then carrying the moveable magnet round and round, but always in the same direction. In this way a very high degree of magnetic virtue may be communicated to each of the *nine* bars. When this is done, they are to be reunited by the screws, and their poles or extremities connected by a piece of soft iron, or *lifter*, or *armature, mn*, as in fig. 80, having at its middle a hook H for suspending any weight. As the lifting power depends on the accurate contact of the poles of the magnets with the lifter, the extremities should, after hardening, be properly rubbed down with putty upon a flat surface.

A magnet of this size and form was found by Professor Barlow to suspend *forty pounds;* but he afterwards found that a greater proportional power could be obtained by using bars that were long in comparison with their breadth.

SECT. X.—*Account of Professor Barlow's method of magnetizing a number of Rectilineal Bars with a Horse-Shoe Magnet.*

Barlow's method of magnetizing bars.

The following method of making artificial magnets is both a simple and efficacious one, and was practised successfully by Professor Barlow:—Having occasion for thirty-six magnets, 12 inches long, $1\frac{1}{4}$ broad, and $\frac{1}{16}$ths of an inch thick, he placed thirty-six bars of steel, of these dimensions, on a table, so as to form a square, having nine bars on each side, the marked or north pole of each bar being in contact with the unmarked or south pole. At the angular points of the square the inner edges of the bars were brought into contact, and the external opening thus left was filled up by a piece of iron $1\frac{1}{4}$th inch square and $\frac{1}{16}$ths of an inch thick. The horse-shoe magnet described in the preceding section was set upon one of the bars, so that its north pole was towards the unmarked end of the bar, and was then carried or rubbed along the four sides of the bars; and the operation was continued till the horse-shoe magnet had gone twelve times round the square. Without removing the magnet, each bar was turned one by one, so as to turn their lower sides uppermost, and the horse-shoe magnet was made to rub along the four sides of the square other twelve times. The bars were then highly magnetized; and the whole process did not occupy more than half an hour.

Methods of making Artificial Magnets.

SECT. XI.—*Account of Knight's method of forming Artificial Magnets with an Iron Paste.*

Knight's artificial magnets of paste.

Although the following method of making a magnetic paste has been given in almost every treatise on magnetism, and was kept a secret by its inventor, yet we have no distinct information that it has been found superior in any respect to steel as a vehicle of magnetism. Mr Benjamin Wilson communicated the method to the Royal Society after the death of Dr Knight.

"Having provided himself with a large quantity of clean filings of iron, Dr Knight put them into a tub that was more than one-third full of clean water; he then, with great labour, worked the filings to and fro for many hours together, that the friction between the filings of iron by this treatment might break off such small parts as would remain suspended in the water for some time; the obtaining of which very small particles in sufficient quantity seemed to him to be one of the principal desiderata in the experiment. The water being by this treatment rendered very muddy, he poured it into a clean earthen vessel, leaving the filings behind; and when the water had stood long enough to become clean, he poured it out carefully, without disturbing such of the iron sediment as still remained, which was now reduced to an almost impalpable powder. This powder was afterwards removed into another vessel, in order to dry it; but as he had not obtained a proper quantity of it by this first step, he was obliged to repeat the process many times. Having at last procured enough of this very fine powder, the next thing to be done was to make a paste of it, and that with some vehicle which could contain a considerable quantity of the phlogistic principle. For this purpose he had recourse to linseed oil in preference to all other fluids. With these two ingredients only he made a stiff paste, taking particular care to knead it well before he moulded it into convenient shapes. Sometimes, while the paste continued in its soft state, he would put the impression of a seal on several pieces, one of which is in the British Museum. This paste was then put upon wood, and sometimes on tiles, in order to bake or dry it before a moderate fire, at about a foot distance. The doctor found that a moderate fire was most proper, because a greater degree of heat made the composition frequently crack in many places.

"The time necessary for baking this paste was generally five or six hours before it attained a sufficient degree of hardness. When that was done, and the several baked pieces were become cold, he gave them their magnetic virtue in any direction he pleased, by placing them between the extreme ends of his magazine of artificial magnets for a few seconds or more, as he saw occasion. By this method the virtue they acquired was such, that when any one of these pieces was held between any of his best ten-guinea bars, with its poles purposely inverted, it immediately of itself turned about to recover its natural direction, which the force of these very powerful bars was not sufficient to counteract."[1] After giving the preceding method, M. Biot remarks, that it consists in procuring a very fine powder of iron a little oxidated, all the particles of which he united by means of linseed oil, or any other substance fitted to give them a proper degree of oxygenation. "When this paste was magnetized," he continues, "each particle of the powder became a small magnet, in which the development of the magnetism might be very powerful, on account of the suitable degree of coercive power produced by the oxy-

---

[1] *Phil. Trans.*, 1779, vol. lxix., p. 51.

Methods of making Artificial Magnets.

genation; and the homogeneity of this state in all the particles, as well as their extreme tenuity, might give to the whole system the most favourable arrangements for receiving a high degree of magnetism." M. Biot conceives that a somewhat analogous effect might be obtained by steel of an equal and homogeneous grain, the carbon giving a coercive power like oxygen; but he thinks that the paste is likely to form better magnets. He is of opinion also that some powerful natural magnets may owe their virtue to the union of similar qualities.

Dr Fothergill, who had seen Dr Knight's paste magnets in his own possession, says that the mass had the appearance of a piece of black lead, though less shining. He informs us also of a very remarkable fact, if it be true, that while the poles of a natural loadstone, or of the hardest steel magnet, could be changed, those of the paste magnets were immoveable. A small piece, of about half an inch square and one-fourth thick, was powerfully magnetic though unarmed; and its poles could not be altered though it was placed between two of Mr Knight's largest and most strongly impregnated magnetic bars.[1]

Conceiving that the powder which formed the basis of this paste was the *black oxide of iron*, or *martial Ethiops*, M. Cavallo has given the following receipt for imitating natural magnets; but he does not say that the magnets made by it are better than those of steel:—"Take some martial Ethiops reduced into a very fine powder, or, which is more easily procured, *black oxide of iron*, the scales which fall from red-hot iron when hammered, and are found abundantly in smiths' shops. Mix this powder with drying linseed oil, so as to form it into a very stiff paste, and shape it in a mould so as to give it any form you require, whether of a terella, a human head, or any other. This done, put it into a warm place for some weeks, and it will dry so as to become very hard; then render it magnetic by the application of powerful magnets, and it will acquire a *considerable* power."

The idea of constructing magnets in this manner may have been suggested by a fact described in the *Memoirs of the Academy of Science* for 1731. A bell, about 400 years old, was suspended at Marseilles by an iron axis resting on stone blocks. Great quantities of rust were thrown off from this axis from time to time, and these particles mixing with those of the stone and the oil which lubricated the pivots, formed a hardened mass which had all the properties of a native magnet.

SECT. XII.—*Account of the method of Arming and Preserving Natural and Artificial Magnets.*

On arming and preserving magnets.

We have already stated, that when a piece of soft iron is suspended at the pole of a magnet, this piece of iron is rendered magnetic, and that a second and a third smaller piece of iron suspended from the other piece of iron also become magnetic, the magnet developing magnetism in the first piece of iron, the first piece developing it in the second, and so on. Each piece of iron reacts as a magnet on the larger piece on which it hangs, improving or increasing the development of its magnetism. Hence the lifting power of a magnet may be increased by suspending to one of its poles, day after day, a small additional piece of iron.

On this property is founded the method of arming natural and artificial magnets, for the purpose both of increasing and preserving their magnetic power. In order to support the greatest weight with any magnet, both its poles should be brought into action. In the horse-shoe magnet this is easily done, so that the *armature* for it is made by merely placing a piece of soft iron *mn* upon its poles A (north) B (south), having a hook attached to it for hanging on weights, as in fig. 80. That the power of this magnet is not only increased but preserved, is easily proved; but the following striking experiment of Mr Watkins affords the most beautiful illustration of the principle. He magnetized a horse-shoe bar *of soft iron*, made of a bar nineteen inches long and one inch square, when its poles A, B were joined by another piece of iron *mn*, and he found that it preserved its magnetic virtue for a long time[2] while its poles were thus united. The moment, however, that the armature *mn* was removed, the magnetism of the horse-shoe bar almost wholly disappeared.[3]

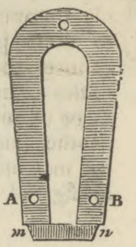

Fig. 83.

Methods of making Artificial Magnets.

The bes tarmature for a natural magnet is shown in the annexed figure, where L, L′ are two broad pieces of soft iron applied to the poles, and projecting on one side of it. To these projecting ends or transferred poles A, B, a piece of iron *mn* is applied, so as to touch them both, as in the horse-shoe magnet in fig. 80. The lateral pieces of iron L, L′ are commonly held firm to the magnet by means of a box of brass, silver, or copper, *ccc′c′*, and the magnet is then said to be armed, the pieces of iron L, L′, A, B, constituting its arms or armature.

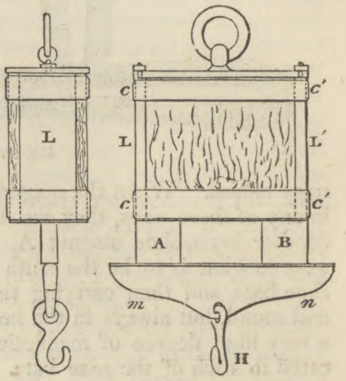

Fig. 84.

A loadstone armed in the preceding manner may be strengthened by Professor Barlow's method of magnetizing horse-shoe magnets; and if we suspend a scale or bag from the hook H, and add, day after day, some additional weight, it may be made to suspend *two* or *three* times the weight that it could lift if applied to it at once. If its force, however, is overpowered by too great a load, its strength will revert to what it was at first; but if we take out of the scale a certain part of the load which it can suspend, we may again proceed to add more weight gradually, till it carries its maximum load.

In order to preserve loadstones and magnets, their armature should always be applied to them. They should be kept in a cool place, free from vibrations, and rough treatment of every kind. Bar-magnets should always be kept with their dissimilar poles together; and both single magnets and needles will have their power not only preserved, but increased, by keeping them surrounded with a mass of dry filings of soft iron, each particle of which will react, by its induced magnetism, upon the point of the magnet to which it adheres, and maintain in that point its primitive magnetic state.

SECT. XIII.—*Account of the method of making Temporary Bar-Magnets of Soft Iron under the influence of Electric Currents.*

Electro-magnets.

In our history of ELECTRICITY we have given some account of the discoveries of M. Arago, Sir H. Davy, M. Savary, and others, relative to the communication of magnetism to steel by ordinary electricity. The subject will be resumed under the article VOLTAIC ELECTRICITY; but, without anticipating what properly belongs to that science,

---

[1] *Phil. Trans.*, vol. lxvi.

[2] See the following section.

[3] *Phil. Trans.*, 1833, p. 338.

Methods of making Artificial Magnets.

we shall give an account in this section of the method of making bar-magnets of soft iron by the influence of electric currents.

This process consists in winding spirally round a horse-shoe bar of iron ABC a copper wire covered with silk thread. A galvanic current is then made to pass through the bar ABC by two wires W, *w*, communicating with two wooden vessels D, E containing mercury. When the voltaic apparatus consists of a single element, viz., one plate of zinc placed in a copper vessel, and having an area of 5 square feet, the magnet, when armed, as shown at *mn*, may suspend by the hook H 100 kilogrammes (2 cwt.).

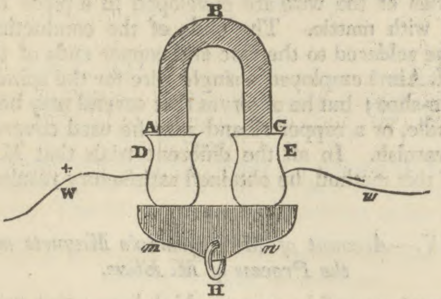

Fig. 85.

M. Moll[1] took a horse-shoe bar 0·22 of a metre high, and 0·025 thick, and rolled round it eighty-three times a copper wire covered with silk, and 0·003 of a metre in diameter. To each of the branches was adapted a counterweight of a pound weight, and projecting a little on both sides. The two extremities of the wire were made to communicate by small vessels of wood filled with mercury, with two elements of a voltaic battery, composed of a bucket of copper, in which was plunged a plate of zinc, whose surface, in contact with the fluid, was 11 square feet. The moment the communication was made, the magnet supported 25 kilogrammes, and with some precautions 38. Another horse-shoe bar, weighing 13 kilogrammes, 0·93 of a metre high, and 55 millimetres thick, lifted 77 kilogrammes. When the direction of the current is changed, the poles of the magnet are instantly reversed; and when the current is stopped, the magnetism of the bar diminishes, though M. Moll found it capable of carrying 25 kilogrammes a quarter of an hour after the current ceased. He found also that the magnetic intensity of the bar was not increased by increasing the number of the voltaic elements or plates; that a horse-shoe of copper was not magnetized; and that a horse-shoe magnet was not rendered more magnetic by the electric current.

Professor Henry.

Professor Henry of Albany Academy had obtained analogous results about the same time with Professor Moll. The apparatus which he used is shown in the annexed figure, which represents a strong rectangular wooden frame 3 feet 9 inches high and 20 inches wide. The magnet A is covered with linen, and the ends of the wires coiled round it all project so as to be soldered to the galvanic element B, which can be plunged into the vessel C, placed on a moveable shelf, and containing dilute acid. D is a graduated lever, E a counterpoise, and F a scale for supporting weights, when the lifting power is not estimated by a small weight sliding upon the lever. The magnet A was fitted up in the following manner:—"A bar of soft iron 2 inches square and 20 inches long was bent into the form of a horse-shoe 9½ inches high; the sharp edges of the bar were first a little rounded with a hammer; it weighed 21 lb. A piece of iron from the same bar, weighing 7 lb., was filed perfectly flat on one surface, for an armature or lifter; the extremities of the legs of the horse-shoe were also truly ground to the surface of the armature. Around this horse-shoe 540 feet of copper bell-wire were wound, in nine coils of 60 feet each. These coils were not continued around the whole length of the bar, but each strand of wire, according to the principle before mentioned, occupied about 2 inches, and was coiled several times backward and forward over itself; the several ends of the wires were left projecting, and all numbered, so that the first and the last end of each strand might be readily distinguished. In this manner was formed an experimental magnet on a large scale, with which several combinations of wire could be made by merely uniting the different projecting ends. Thus, if the second end of the first wire be soldered to the first end of the second wire, and so on through all the series, the whole will form a continued coil of one long wire. By soldering different ends, the whole may be formed into a double coil of half the length, or into a triple coil of one-third the length," &c.[2]

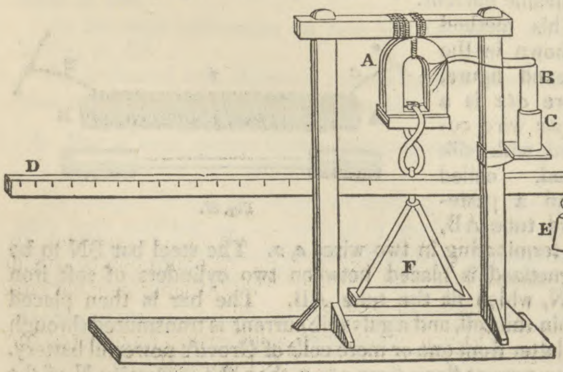

Fig. 86.

Methods of making Artificial Magnets.

In making experiments with this magnet, a small single battery was used, consisting of two concentric copper cylinders, with zinc between them; the whole of the zinc surface in action, including both sides of the zinc, was $\frac{2}{5}$ths of a square foot, and the quantity of dilute acid only half a pint. The following were the results:—

Number of wires soldered to the Battery in succession.		Weight lifted, in pounds avoirdupois.
1.	Each soldered to the battery in succession.....	7
2.	One on each side of the arch..........................	145
2.	One from each end of legs..........................	200
3.	One from each end of legs, and the other from middle of arch..........................	300
4.	Two from each end....................................	507
6.	Wires attached..	570
9.	All the wires attached................................	650
9.	A plate of zinc 12 inches long and 6 wide, and surrounded with copper, substituted for the preceding battery.........................	750

When a pair of plates, exactly *one inch square*, was attached to the wires, the weight lifted was 85 lb.

Professor Henry mentions that this magnet weighed 21 lb., and lifted more than 35 times its own weight; whereas the largest natural magnet known, and in the possession of Mr Peale of Philadelphia, lifts 310 lb., or about six times its own weight.

MM. Lipkens and Quetelet.

MM. Lipkens and Quetelet found that great effects will be produced by small voltaic surfaces, provided that the chemical action is energetic, and that the degree of magnetism depends more on the size of the iron shoes, than on the dimensions of the voltaic plates.[3]

Mr Watkins.

The horse-shoe iron magnets formed by electrical currents are only temporary, and it became interesting to discover the time of duration of the magnetism. Mr Francis Watkins made some interesting experiments on this sub-

Methods of making Artificial Magnets.

ject.[1] He found that when the *armature* or *keeper* is *removed* from the two poles of the magnet, it instantly loses all its magnetism when the electric current is cut off; but that if the *armature* is kept upon the poles, the soft-iron magnet will retain its magnetism for a great length of time. Mr Watkins made a horse-shoe bar with a piece of soft iron 18 inches in length and 1 inch in diameter, and he rendered it magnetic by winding round it in a single helix 20 feet of copper wire $\frac{1}{16}$th of an inch thick. The ends of the copper helix being connected with a single pair of voltaic plates, the horse-shoe, when rendered magnetic by the current, supported 125 lb. The voltaic action continuing, the weight was reduced to 56 lb., and the voltaic plates removed; the weight was also carefully removed, so as not to displace the armature or keeper. The sustaining power of the horse-shoe was then tried every day, and at the end of ten days it sustained 56 lb. as firmly as it did at first. Another horse-shoe bar charged with magnetism in November, was as powerful, and rather more so, in April, than it was at first. After a lapse of fifteen weeks it frequently supported 30 lb. This soft-iron magnet was tried at the Duke of Sussex's house on the 27th of April, *and though nearly six months had elapsed since it received the magnetic virtue, it supported* 100 lb.; but the instant that the *keeper* was separated from the poles, almost all the magnetism disappeared. When the keeper was again applied, there was not enough of magnetism even to support the keeper.

Mr Watkins made some interesting experiments on the lifting powers of soft-iron magnets when plates of mica of different thickness were interposed between the poles and the keeper. The magnet was of the size and shape already stated; but Mr Watkins has not mentioned the successive thicknesses of the mica plates, nor does he state that they were of equal thickness. Had he mentioned the tints which each of them polarized, it would have been easy to compute their exact thicknesses. The following were his results:—

Number of Plates of Mica interposed.	Number of Pounds supported besides the Keeper.
1	49
2	40
3	26
4	17
5	13
6	8
7	4½
8	2½
9	2
10	1½
11	1
12	0¾
13	0½
14	The keeper only.
15	0

When a piece of common *writing-paper* was placed between the poles and the keeper, 28 lb. were supported by the magnet. Hence a piece of writing-paper was equal to *three* plates of mica.

SECT. XIV.—*Account of M. Aimé's method of making Permanent Artificial Magnets.*

Aimé's method.

A method of inducing magnetism, published by M. Aimé,[2] is one equally simple and efficacious. It is founded on the facts described in the preceding section, and consists in holding a bar of red-hot steel with pincers between the two poles N, S of a horse-shoe magnet rendered magnetic by an electrical current. The horse-shoe and the included bar, which should exactly fit the space between the poles, are then plunged in cold water, and kept there for a little time, depending on the size of the real magnet, till the bar is thoroughly cold along its axis. In order to prevent the brass spiral wire that is curled round the horse-shoe bar from being wetted when the apparatus is under water, the extremities of the wire are enveloped in a piece of linen covered with mastic. The ends of the conducting wire should be soldered to the zinc and copper ends of the battery. M. Aimé employed a single wire for the spiral round the horse-shoe; but he observes that several may be united in a bundle, or a copper riband may be used covered with silk or varnish. In all the different trials that M. Aimé made of this method, he obtained satisfactory results.

Methods of making Artificial Magnets.

SECT. XV.—*Account of M. Logeman's Magnets made by the Process of M. Elias.*

Logeman's magnets.

The most powerful magnets which have come under our notice are those of M. Logeman, optician, Haarlem, made by the process of M. Elias of the same town, who, like M. Aimé, availed himself of the magnetism produced by electrical currents. In the Great Exhibition of 1851, M. Logeman exhibited three magnets, which weighed respectively 43·6, 2·75, and 0·475 kilogrammes, or nearly 96, 5·75, and 1 lb. English. These magnets supported the following weights:—

Weight of Magnet.	Force of Magnet or weight supported.
96 lb.	232 lb.
5¾ „	45½ „
1 „	29 „

According to M. Haecker,[3] who made numerous experiments with various magnets, their force is proportional to the cube root of the square of their weight; and that if W is the weight of a magnet, and F its force, or the weight which it will support, then

$$F = 10{\cdot}23\ W^{\frac{2}{3}}$$

will represent the force of the best magnets made in Europe. It is obvious, however, from the above table, that the force of M. Logeman's magnets is nearly double of that given by the formula of Haecker. The following are the weights, forces, and prices of other magnets made by M. Logeman:—

Weight.	Force.	Price.
1 lb.	29 lb.	—
12½ „	150 „	L.8
52 „	430 „	20

The process of M. Elias by which these magnets were made, consists in making the magnet, with its armature attached, pass through a copper wire helix traversed by a galvanic current.

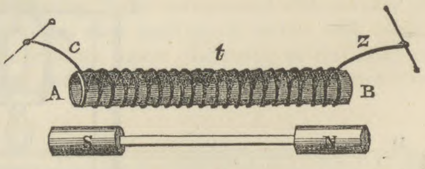

Fig. 87.

This method is shown in the annexed figure, where *ctz* is a copper wire covered with silk thread, coiled round a pasteboard tube AB, and terminating in two wires *c*, *z*. The steel bar SN to be magnetized is placed between two cylinders of soft iron S, N, which fit the tube AB. The bar is then placed within the coil, and a galvanic current is transmitted through the latter from one or more cells of Grove's powerful battery. If the current flows from *c* to *z*, then the extremity N of the bar will be a north pole.

M. Logeman has also applied the process of Elias in the construction of compass-needles, one of which was exhibited in 1851. In consequence of their greater magnetic power, these needles have a greater directive power, are less affected by the motions of the ship, and are useful in high latitudes where the ordinary compasses are of no service.

Sect. XVI.—*Account of the Experiments made by Coulomb and Kater, on the efficacy of the different methods of making Artificial Magnets.*

Coulomb's comparison of different methods.

Coulomb was the first person who examined experimentally the value of the different methods of making artificial magnets. The following is a brief abstract of his results:—

1. *Wires of tempered steel twelve inches long and one-twentieth of an inch in diameter.*

When rubbed at right angles on the pole of a single artificial magnet, it performed 10 oscillations in 74^s.

When rubbed at right angles upon the poles of 4 united bar-magnets, or magnetized by the methods of Duhamel and Æpinus, it performed the same number of oscillations in the same time. Hence *small* steel wires attain their maximum degree of magnetism equally well by all the different methods.

2. *A plate of annealed steel twelve inches long, one-third wide, and one forty-second of an inch thick.*

When rubbed at right angles on a single pole, it performed 10 oscillations in 77^s.

When rubbed on *two* united poles, 10 oscillations in 75^s.

When rubbed on *ten* poles, 10 oscillations in 75^s.

By the methods of Duhamel and Æpinus, 10 oscillations in 75^s.

The effect of the different methods is now perceptible, the first being the worst.

3. *A plate of steel six and a half inches long, nine twenty-fifths wide, and one forty-second thick.*

When rubbed on 2 poles, 10 oscillations in 51^s.

Upon 5 poles, 10 oscillations in 49^s.

Upon 8 and 10 poles, 10 oscillations in $47\frac{1}{2}^s$.

By Duhamel's and Æpinus's methods, 10 oscillations in $47\frac{1}{2}^s$.

4. *A plate eight inches long, fourteen twenty-fifths wide, and one twenty-fifth thick.*

When rubbed upon *one* pole, 10 oscillations in 73^s.

Upon *four* poles, 10 oscillations in 62^s.

Upon *ten* poles, 10 oscillations in 59^s.

At an inclination of 15° or 20°, on *two* poles, 10 oscillations in 53^s.

At the same inclination on *four* and *ten* poles, 10 oscillations in 49^s.

By Duhamel and Æpinus's methods, with *one* or more bars on each side, 10 oscillations in 49^s.

5. *Bar of steel sixteen inches long, six-tenths wide, and one-fifth thick.*

By magnetizing it on Æpinus's method, with *two* moveable bars rubbing on its surface, it performed 10 oscillations in 110^s, and was found to be saturated. By Duhamel's method it required moveable bundles of 4 bars each.

6. *Bar of steel sixteen inches long, one inch broad, and nine twenty-fifths thick.*

When magnetized by Æpinus's method, with bundles of 4 or even 10 bars, it performed 10 oscillations in 153^s.

But by Duhamel's method, with even *ten* bars, it only performed 10 oscillations in 162^s.

Hence the magnetic force communicated by the first method was to that of the second as 9 to 8.

Directive force of needles.

Captain Kater made a series of interesting experiments on the directive force of needles, produced by different methods of magnetizing them. The needles which he used were right-angled parallelograms, 5 inches long, the one $\frac{7}{10}$ths of an inch broad, and the other $\frac{7}{20}$ths. The broadest was made thinner till it had the same weight as the other, which was 142 grains. The following table contains the result of the experiments:—

	Directive Force.	
	Small Needle.	Large Needle.
1. The magnets placed perpendicularly on the centre of the needle, and the needle rubbed from end to end on both sides	655	674
2. The same, but the magnets separated at top in the same way as at bottom	595	580
3. The same as No. 1, but the distance of the lower end of the magnets 2½ inches	760	780
4. The magnets joined on the centre of the needle, and each moved towards the nearest pole, then lifted up and joined again, and so on	993	1155
5. The magnets being joined on the centre of the needle, their lower ends were made to move to each pole, their upper ends remaining in contact	1025	1150
6. By Duhamel's method, the magnets inclined 45° to the needle, and moved from the centre to the poles	1070	1170
7. The same, but the inclination of the magnets 20°	1085	1195
8. The same, but the inclination only 2° or 3°	1160	1275
9. Magnets laid flat on the needle, and drawn from the centre to the end	1158	1261
10. Same as No. 8, but the separated ends of the magnets connected by an iron wire	1145	1261
11. Wire removed, and experiment No. 8 repeated	1260	1273
12. Needles hardened at a bright red, and then softened from the centre to within $\frac{3}{4}$ths of an inch of their extremities, and magnetized as No. 8	1815	1665

Captain Kater next ascertained the effect of length on the directive power of needles. He cut two needles of equal weight out of the same plate of steel, the one being 5, and the other 8 inches long.

13. Magnetized to saturation as in No. 8	1893	2275
14. Hardened and tempered beyond the blue, from the middle to within an inch of the poles	1865	2277

Hence it follows, as Coulomb had ascertained, that the directive force of needles whose length exceeds 5 inches is probably as their lengths.[1]

CHAP. XI.—DESCRIPTION OF MAGNETICAL INSTRUMENTS.

Magnetical instruments.

The great importance and value of magnetical instruments, not only in the arts of navigation and surveying, but in the determination of the various and ever-changing phenomena of terrestrial magnetism, renders it necessary that we should enter with some detail into this branch of the subject. As a magnetic needle constitutes the principal, if not the essential part, of the greater number of magnetical instruments, we shall begin our observations with some details respecting the forms, description of steel, temper, and construction of magnetic needles.

---

[1] *Phil. Trans.*, 1821, p. 104.

Description of Magnetical Instruments.

SECT. I.—*On the best Form and Construction of Compass Needles.*

The most valuable experiments on this subject are those made by M. Coulomb and Captain Kater. Those of Captain Kater are particularly important.

Form, &c., of compass needles.

With regard to the material out of which the needle should be formed, Captain Kater found that needles of *shear steel* received a greater magnetic force than those of *blister steel*, or *spur steel*, those of *cast iron* being much inferior to the others.

Coulomb's experiments.

The next object of inquiry was to ascertain the form of the needle which is best suited for receiving the greatest directive power. The forms which have been generally used are, the cylindric, the prismatic, that of a rhomb or a parallelogram, and that of a flat bar which tapers to its extremities like an arrow. According to the experiments of Coulomb, the form last mentioned, "*une lame taillée en flèche,*" was the best, and was susceptible of a greater directive power than those which had the form of a parallelogram. He found that any expansion of the needles towards these poles was accompanied with a loss of power; and he drew the general conclusion, that in needles of the same form, their directive forces are proportional to their masses. Captain Kater likewise found that the directive force was little, if at all, influenced by the extent of its surface; but that it depended almost wholly on the mass of the needle when it was saturated with magnetism.

Captain Kater's experiments.

Captain Kater compared needles that had the form of a wide and a narrow rectangular parallelogram, and a small rhombus, a large rhombus, and a pierced rhombus, and he found that the form of the pierced rhombus is decidedly the best. A needle of this form (the sides of the rhombus are a little rounded in the figure), as made by Dollond, is shown in fig. 88, the cross piece at the centre being made of brass or copper.

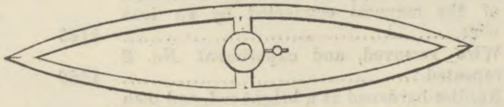

Fig. 88.

With regard to the best mode of hardening and tempering needles, Captain Kater found, that when a needle is considerably hardened throughout, its capacity for magnetism is diminished. He found that the needle was susceptible of the greatest directive power when it was first hardened uniformly at a red heat, and then softened from the middle to within an inch of its extremities, by using a degree of heat which is just capable of making the blue colour, which is thus produced, to disappear. Captain Kater likewise found that the polishing of the needle, previous to its being touched, had no advantage; and that an increase of pressure of the touching magnets on the needle was sometimes injurious, and never useful.

When the needle is magnetized, it has a cap *cc* fitted into the opening in its centre, seen in fig. 89, and about ¼th of an inch in diameter. This hollow cap is executed with great care, and is generally made of agate (garnet is much better). The interior curved surface, particularly the summit of it, requires the best workmanship. This summit rests on the pivot *n*, the point of which is wrought to an angle of from about 15° to 20°.[1] The use of the ring *aa* is to raise up the cap of the needle, and take it from the pivot when it is not in use. The rod or handle *r* of this ring is continued to the outside of the compass-box, where it can be put in motion, so as to disengage the needle from its pivot, or replace it at pleasure.

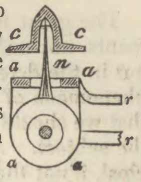

Fig. 89.

When a compass-needle is nicely balanced on a pivot, previous to its being magnetized, so as to traverse freely in a horizontal plane, it will no longer do so after it has been rendered magnetic. One of its ends will preponderate, in consequence of the tendency of the needle to dip, or place itself in a position parallel to the magnetic axis of the globe. In order to restore its equilibrium, therefore, it is necessary to add a small weight to one side of the needle, as shown in fig. 88. The weight requisite for this purpose will increase with the dip, so that it may be necessary to slide the weight farther from the centre in going towards the magnetic poles, and *vice versa*.

As the needle of ordinary compasses is generally placed upon a card on which the various points of the compass are marked, in stormy weather it is necessary to give weight to the card, to preserve it steady during irregular motions of the vessel. Various contrivances have been adopted to remedy this evil. The usual method is to load the card with sealing-wax. Some place pieces of paper, like vanes, on the lower side of the card, to act against the air, and check the vibrations; while others have proposed to make the needle move in oil or other liquid, with the same view. The consequence of these contrivances is, that while the weight of the card, or its resistance to motion, is increased, the directive power of the needle remains the same, so that in getting rid of one evil, another of greater magnitude is created. The mobility of the needle is diminished, and the steersman may mistake his course by trusting to the apparent steadiness of his compass. The simplest remedy for this evil is to use a heavier needle, with a greater directive power, or by combining several needles together.

Professor Barlow's card.

The latter idea was proposed by Professor Barlow, who constructed the card as shown in the annexed figure, where NESW is the card, and NS, N′S′, N″S″, *ns*, *n′s′*, five parallel needles placed at equal distances. Professor Barlow showed that the directive force of this combination of needles is nearly *four* times greater than that of a single needle; but as the weight and friction on the pivot is increased nearly in the same proportion, no other advantage is gained but the proposed one (particularly requisite in boat compasses) of making the cards steady by their additional weight, while the relative directive power remains the same.

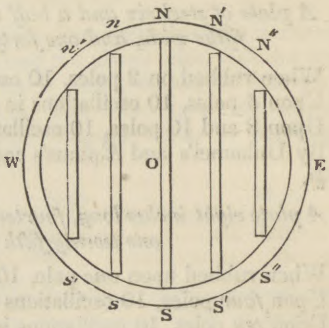

Fig. 90.

SECT. II.—*Description of the Common and Azimuth Compass.*

Compasses.

The common compass, whether it is called the *mariner's compass* or the *land compass*, serves only to point out the direction of the magnetic meridian, while *azimuth* compasses enable us to determine the angular distances of objects from the magnetic meridian.

Common.

The common compass consists of a needle fixed to a circular card, containing upon its surface the thirty-two points of the compass. This card is balanced, as already described, upon a pivot fixed in the bottom of a circular box, and the top of the box is a plate of glass for protecting the needle from motions of the air. This compass-box,

---

[1] Coulomb, *Mém. de l'Institut.*, tom. iii., has shown that this is the best angle for pivots.

Description of Magnetical Instruments.

shown at AB, fig. 91, is suspended within a larger box PQ, upon two concentric brass circles or gimbals, the outer circles being fixed by horizontal pivots both to the inner circle, which carries the compass-box, and likewise to the outer box, the two axes upon which the gimbals move being at right angles to each other. The effect of this construction is, that the compass-box AB will retain a horizontal position during the motions of the vessel.

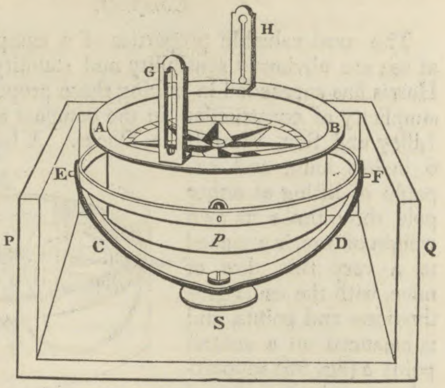

Fig. 91.

Azimuth compass.

The azimuth compass, shown in fig. 91, differs from the common compass principally in its being furnished with sights G, H, through which any object may be seen, and its angle with the magnetic meridian increased. For this purpose the whole box is hung in detached gimbals CD, EF, which turn upon a stout vertical pin, seen above S. In some instruments, the sights G, H may be turned down by a joint over the glass when the compass is not in use, as shown in fig. 92; and in others they are connected by a brass bar, and may be taken from the compass when they are not wanted. In this compass, the card is divided on its rim into 360°; but the divisions are more frequently placed on a light metallic rim which it carries. The eye is applied to the sight H, which is a slip of brass containing a narrow slit. The other sight G, which is turned towards the object, contains an oblong aperture, along the axis or middle of which is stretched a fine horse hair or wire, which is made to coincide with or pass over the object or point whose angular distance or *azimuth* from the magnetic meridian is to be determined.

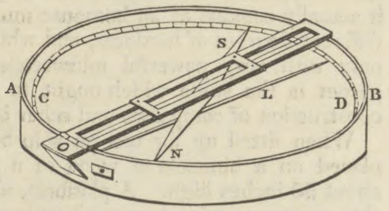

Fig. 92.

It is extremely difficult, when the ship is in motion, for the same person to take the bearing of the object and read off the angle; and various contrivances have been adopted to remedy this great defect. One of these is to have on one side of the compass-box a nut, which, when pressed by the finger, pushes a lever against the card, and stops its motion, so as to allow the angle to be read off at leisure; but a false reading is often obtained with this contrivance.

SECT. III.—*Account of Captain Kater's Azimuth Compass.*

Kater's azimuth compass.

This ingenious compass may be regarded as a universal instrument capable of being advantageously used both at sea and on land. It is represented in detail in figures 92, 93, and 94. In fig. 93, AB is a cylindric box made of brass, one inch deep, and covered with glass, and contains a card CD, 5 inches in diameter. The needle NS has an agate cap set in brass, and fixed in its centre. The needle is fixed to a circular piece of talc, on the circumference of which is laid a narrow ring of card, which is graduated to half degrees on its outer margin. On the inner side of the box there is fixed a standing piece of ivory, which just projects over the outer margin of the graduated circumference of the card, and an index-line is engraved on the ivory as a point of departure for reading off the divisions on the card. A brass sight-frame GH is fixed by a hinge at H, on the opposite side of the box. It has the form of a parallelogram, and is 5 inches long. A frame EF, 2 inches long, slides up and down upon GH, and contains the segment of a glass cylinder, whose radius is 5 inches. When the solar rays fall upon this cylindrical bar, they are collected into foci which form a line of light which is thrown upon the index-line of the piece of ivory, and which may be seen at the same time as the divisions on the card. The frame GH, when folded down, as shown in fig. 92, acts upon a lever L, which raises the needle NS, and prevents it from traversing by pressing it against the glass cover.

Description of Magnetical Instruments.

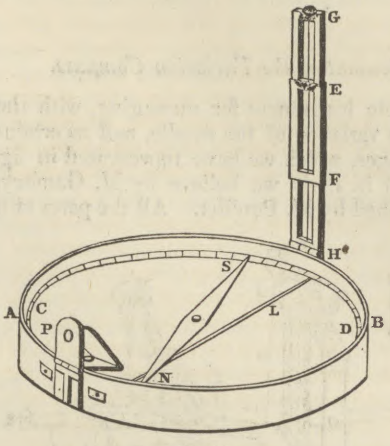

Fig. 93.

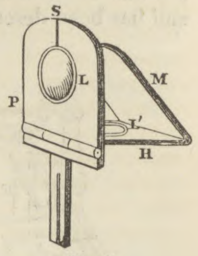

Fig. 94.

The sight-hole to which the eye applies itself is shown at P, figs. 93 and 94. It is an inch from its hinge to its summit, but may be raised higher by means of grooves, in which a branch below the joint covers it, as seen in the figure. The upright plane P has a slit S terminating below in a circular aperture, which receives a convex lens. To this is fixed a horizontal plane H, having a lens in its centre; and above this, inclined to it at an angle of 45°, is placed a mirror M, by means of which and the lenses, an eye looking through the lens below S sees magnified the divisions on the card, distinct vision being produced by sliding the sight upwards or downwards.

In order to take the sun's azimuth, raise the object-sight GH, and slide the cylindrical lens EF till its luminous line or focus falls upon the index. The eye-glass sight P is then to be moved up and down till it gives distinct vision of the index-line on the ivory. If the line of light is not narrow and well defined, incline the sight GH towards the compass till it is so, care being taken that the sight is perpendicular to the horizon, between the observer and the sun. When this is effected, incline the compass to the observer, so as to check the oscillations of the card by bringing it in contact with the index and two pins fixed near it for the purpose. When the card is made steady by the repetition of this, taking care that the compass is inclined as much from the observer as will just free the card from the index, and that the line of light is bisected by the index-line, this lens will indicate on the card the azimuth of the sun required, which, when the correction on the card is applied to it, will give the true azimuth of the sun from the magnetic meridian; and by means of this element and the observed altitude, the variation of the needle may be obtained in the usual way.

In using this compass for surveying, the cylindrical lens is slid to the top EG, and the hair or wire GH is then seen; and when this hair is made to bisect any object seen by direct vision, we have only to read off the azimuth of that object as seen on the card viewed by reflection.

Description of Magnetical Instruments.

By turning back the reflecting sight P round its hinge, the line of light may be viewed on the index, and the angle read off by direct vision, a mode of observation which has its advantages.

SECT. IV.—*Account of the Variation Compass.*

Variation compass.

The very complete instrument for measuring, with the nicest accuracy, the variation of the needle, and ascertaining its diurnal changes, which we have represented in fig. 95, was constructed in Paris, we believe by M. Gambey, and has been described by M. Pouillet. All the parts of it which are of metal are executed in copper. A table NN of white marble supports the pillars and case of the instrument. The columns C, D, are those by which the needle is suspended, and E, F, G, H, those which support the microscopes M, M′. The box of the needle is shown at BB′, and the needle itself AA′ is placed in the small copper ring *op*, to which is fastened a wire or a number of silk threads without torsion, which suspend the needle, and which may be rolled round the small cylinder seen between *c* and *d*, and turned round by the milled head *e*. This wire is kept in the centre of the little graduated circle *cd*, by crossing at that centre a small triangular aperture. The wire is inclosed in a small cage of glass, which rises between the two columns C, D, in order that the air may neither be agitated nor penetrate into the box. By turning the milled head *e*, the needle AA′ may be raised or depressed at pleasure. Two moveable panes of glass shut up the apertures A, A′ of the box, which are above the two ends of the needle. Upon each of the extremities of the needle there is firmly fixed a small plate of ivory *mn*, *m′n′*, bearing a very minutely divided scale, each of the divisions having the angular value of 15′ or 20′.

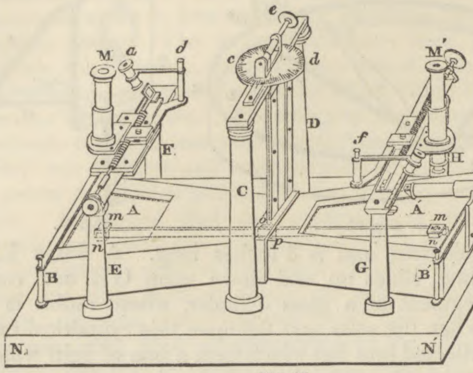

Fig. 95.

When the apparatus has been placed as nearly as possible in the plane of the magnetic meridian, and carefully levelled, we must see that the silk thread is without torsion; and by a few trials the microscopes M, M′ may be directed so as to see the zero or index of the ivory scales at the ends of the needle. It is then easy to observe the displacements which the needle experiences, either by counting the divisions which have passed under the wire of the microscope, or by following its motions by means of the screw by which the microscopes are moved. Small microscopes, one of which is shown at *a*, and moveable round the rods *b*, *f*, are used to read off the position and course of each microscope M, M′ along the bar which carries it, and which regulates its lateral motion.

The telescope T is used for counting more conveniently, and consequently more correctly, the oscillations of the needle, when we wish to employ it for measuring the magnetic intensity. It carries before its object-glass a mirror, which reflects the vertical rays along the axis of the telescope.

SECT. V.—*Description of Sir William Snow Harris's Compass.*

Harris's compass.

The most valuable properties of a compass to be used at sea are obviously sensibility and stability. Sir William Harris has succeeded in uniting these properties with great simplicity of construction, in the compass made by Messrs Lilley and Son, West India Docks. A bar-needle, about 6 inches long, and capable of lifting at either pole three times its own weight of iron, is attached to a very thin disc of mica, with the usual graduations and points, and is balanced on a central point *c* (fig. 96) supported by a double curved bar, *anb*, fixed to a dense ring of copper *acbd*, so that the poles almost touch the ring. This ring, as discovered by M. Arago, exercises such an electro-magnetic action upon the needle, that it soon brings it to rest when it has been made to vibrate by the motion of the ship or any other cause. In heavy seas the oscillation was found not to exceed from one-fourth to half a point each way, and in screw propellers the compass proved particularly steady. In some of these compasses, which are now extensively used, defects have been found from the abrasion of the agate centre, and in such cases the agates were found defective. The agate is certainly the worst of the hard minerals that are fitted for pivots of any kind, as it actually consists of an immense number of thin strata of different degrees of hardness, and which can often be seen only with very powerful microscopes. The Greenland garnet is the stone which ought to be employed in the construction of compasses and other instruments.

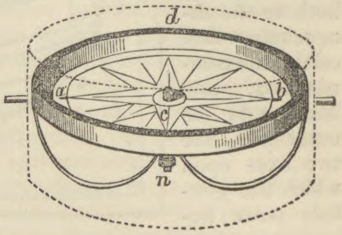

Fig. 96.

When fitted up for use on ship-board, this compass is placed on a binnacle of wood of a cylindrical form, and about 30 inches high. A platform, about 20 inches below the compass, carries two small spring candle lamps, which throw their light upon the transparent card, and illuminate it efficiently and economically at night.[1]

SECT. VI.—*Description of Mr Swan's Simple Variation Compass.*

Swan's variation compass.

A new variation compass was constructed in 1852 by Mr John Adie, Edinburgh, for the purpose of measuring the declination of the needle more accurately than by ordinary compasses. It consisted of a delicately suspended compass-needle, inclosed in a tube furnished with collars, which are placed in the Y's of a theodolite, after the telescope has been removed. The ends of the needle, being made sharp points, are brought nearly into contact with finely divided glass diaphragms, and by means of powerful eye-pieces, the place of the needle is determined. Being desirous of having a contrivance of the same kind applied to a Kater's altitude and azimuth circle which he possessed, Mr Swan was obliged to adopt an arrangement totally different from Mr Adie's, as the telescope of his circle did not admit of

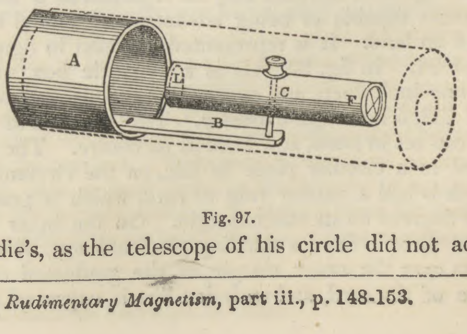

Fig. 97.

---

[1] A fuller description of this compass will be found in Harris's *Rudimentary Magnetism*, part iii., p. 148-153.

Description of Magnetical Instruments.

being removed. In figure 97, A is a collar fitted to slide without much friction upon the object end of the telescope of the theodolite with which it is to be used, B an arm projecting in front of the telescope, and having a fine steel point C, and LF a small collimating magnet, having an agate cap, which moves upon the point C. The magnet should be a hollow cylinder, carrying at one end an achromatic lens L, and at the other a cross of spider lines F. These lines being in the focus of the lens L, will be seen distinctly by the telescope. The magnet is protected from currents of air by a light tube of copper or brass, shown by dotted lines, in the outer end of which is an aperture covered with glass, through which a small reflector throws light upon the cross wires. For further information consult Mr Swan's papers in the *Transactions of the Royal Scottish Society of Arts*, vol. iv.; also *Transactions of Royal Society of Edinburgh*, vol. xxi., part ii., *On Errors caused by Imperfect Inversion of the Magnet in Observations of Magnetic Declination.*

SECT. VII.—*Description of Colonel Beaufoy's Variation Transit.*

Beaufoy's variation transit.

This instrument, which was employed by Colonel Beaufoy in the valuable series of magnetic observations which he made between the years 1813 and 1821, is represented in perspective in fig. 98, where FF is a mahogany board, which forms the support of the instrument, resting on three screws G, H, I, by which it can be levelled. Above this is a flat plate of brass EE, fixed to the board by a centre pin, and resting upon three studs projecting from the board. It has a small horizontal motion round the centre pin, by means of the screw W and milled head X. The plate EE carries the graduated arc *m*, which is subdivided by the vernier D projecting from the box *ddd*, containing the needle AA. This box moves on the common centre pin of the plate EE. In the plate which carries the vernier D is fixed the frame *aab*, which is furnished with a clamp-screw L to fasten it to the arc *m*, and a tangent screw K, by which the box *ddd* can be moved round its centre pin.

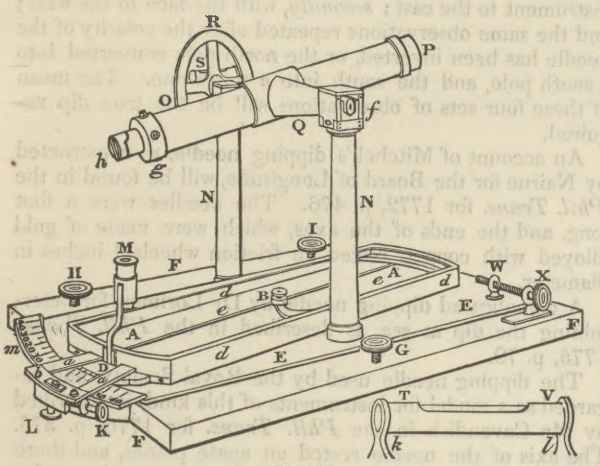

Fig. 98.

The centre pin of the box *dd*, and plate EE, terminates in a very fine pivot, on which the needle AA is suspended by means of an agate cap B, for diminishing the friction. The needle AA, which is a cylinder, is 10 inches long and $\frac{1}{500}$th of an inch in diameter. It weighs sixty-five grains, and is terminated by two conical points; and it is furnished with the usual lever, &c., for lifting it from the pivot of suspension and lowering it again. There are within the box *dd*, and beneath the ends A, A of the needle, two segments of brass, which have the centre lines drawn upon them; and these lines are brought to the points of the needle when the observation is made, by observing the coincidence through the double microscope M, which can be removed to the opposite end of the box.

Description of Magnetical Instruments.

The transit telescope OP rests on two pillars N, N, fixed on the brass plate EE, and having at their summits small boxes *f* for the reception of the Y's, in which the pivots of the conical axis Q of the telescope are supported. At the end of one of the pivots of this axis is fixed a small divided circle R, on an arm of which, provided with a level S, are placed the verniers for reading off the divisions. The eye-piece *h* admits a dark glass for solar observation, and the wires of the eye-piece are adjusted by screws at *g*. There is also a detached level TV, whose feet *k*, *l* are placed in different directions upon the plate EE, for the purpose of levelling it. The use of the telescope is for finding the true meridian by means of the sun or stars, and the meridian should be indicated by fixed meridian marks.

When the instrument is properly levelled, and the telescope placed in the true meridian, the needle is allowed to settle, and the box *dd* is turned upon its centre till its mark comes near the point A of the needle. The clamp-screw L is then fixed to the arc *m*, and the screw K is turned till the coincidence of the index with the point of the needle is seen through the microscope M to be perfect. The vernier D will then show the exact angle of variation, or the declination of the needle from the true meridian.

SECT. VIII.—*Account of Dollond's Variation Transit.*

Dollond's variation transit.

This instrument is shown in fig. 99. A brass pedestal CD, supported by three screws for adjusting it horizontally, forms the foundation of the four pillars which support the transit telescope AB, on the axis of which is fixed the graduated circle E, provided with all the usual contrivances for the accurate adjustment of the axis of the transit, and with microscopes for reading off the degrees. A cap or cover, seen separately at *a*, and containing a lens, is placed before the object-glass of the telescope, in order to convert it into a transit microscope; the focus of the lens being suited to the distance of the needle, seen between C and D, and the divisions of the graduated circle in the compass-box CD; the centre of the lens corresponding accurately with that of the object-glass. By this method the correct place of the divisions, as well as of the needle, may be readily ascertained, and the extreme deviation, as well as its diurnal changes, accurately determined. This instrument may also be used as a theodolite, and employed also for taking altitudes and equal altitudes.

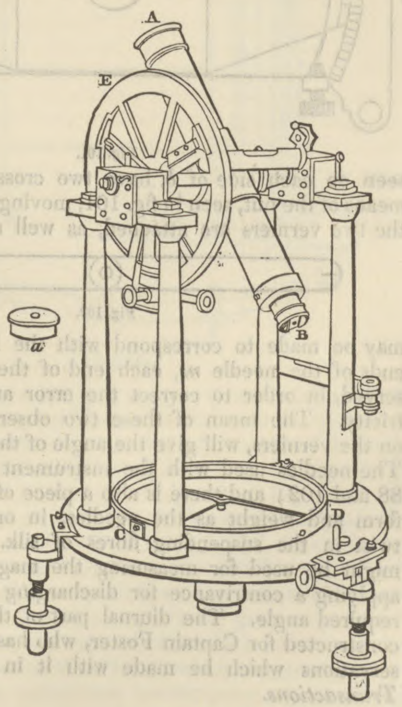

Fig. 99.

SECT. IX.—*Description of Dollond's Diurnal Variation Instrument.*

This instrument is shown in figs. 88, 100, 101, and 102.

Dollond's diurnal variation instrument.

It is made of mahogany and ivory, in order to avoid the attraction supposed to reside in all the metals. The needle *ns* is supported by the silk fibre *cbd* passing over a pulley at *b*, and counterpoised by a ball *d*. The two microscopes, seen on each side of *b*, have two cross wires, which, by means of the nut, seen in fig. 101, moving the frame to which the two verniers are attached, as well as the microscope, may be made to correspond with the index-lines on the ends of the needle *ns*, each end of the needle being observed, in order to correct the error arising from eccentricity. The mean of these two observations, as read off on the verniers, will give the angle of the diurnal variation. The needles used with the instrument are shown in figs. 88 and 102; and there is also a piece of brass, of the same form and weight as the needles, in order to detect any twist in the suspending fibres of silk. This instrument might be used for measuring the magnetic intensity, by applying a contrivance for discharging the needle at the required angle. The diurnal part of this instrument was constructed for Captain Foster, who has published the observations which he made with it in the *Philosophical Transactions.*

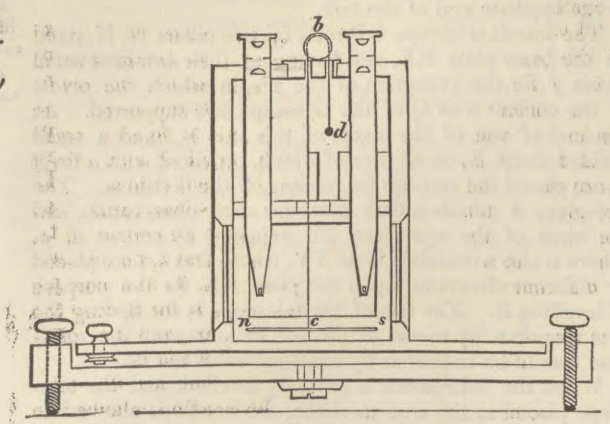

Fig. 100.

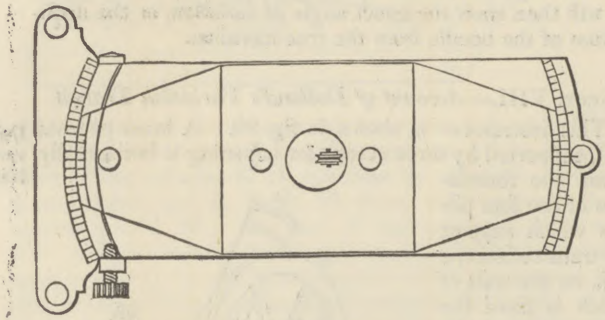

Fig. 101.

Fig. 102.

Sect. X.—*Description of the Dipping Needle as constructed by Messrs Gilbert.*

Gilbert's dipping needle.

After the dip of the needle was observed, and its changes discovered, instruments of various forms were contrived and used, under the name of *dipping needles*, for measuring the dip or inclination of the needle to the horizon. One of the most complete of these instruments, as constructed by Messrs W. & T. Gilbert, is shown in fig. 59, in perspective. It consists of a brass plate CAB, supported by three screws A, B, C upon a flat board or stand. In the centre of this brass plate is another ED, concentric with the former, and moveable round a centre pin like the moveable plate of a theodolite. This plate ED carries two levels at D for adjusting the plate horizontally. Four supports, shown at E and F, carry the circular box HGP, or principal case of the dipping needle NS. Two equal brass bars, one of which is seen at KL, are firmly fixed across the case in a horizontal direction. Other two brass pieces *m*, *n* are fixed by screws to the centre of the bars K, L, and carry two finely polished planes of agate, on which the axis of the needle NS rests, and upon which it turns freely. There is a contrivance inside the box G, and on the other side of KL, not seen in the figure, by which the observer, by turning the milled head P, can lift, by means of Y's, the needle from the agate planes, or lower it upon them, at pleasure; the Y's being carefully adjusted, so as always to leave the axis of the needle on the same part of the agate planes, and in the centre of the divided circle. In this instrument the ends N, S of the needle are graduated so as to act as a vernier scale for subdividing the degrees of the divided circle into 6′. A microscope is attached to the rim of the glass face, so as to be easily placed on any part of it, for the purpose of reading off the dip. In this instrument the length of the needle NS is six inches.

In order to obtain an accurate measure of the dip, several measures of it should be taken; *first*, with the face of the instrument to the east; *secondly*, with the face to the west; and the same observations repeated after the polarity of the needle has been inverted, or the north pole converted into a south pole, and the south into a north one. The mean of these four sets of observations will be the true dip required.

An account of Mitchell's dipping needle, as constructed by Nairne for the Board of Longitude, will be found in the *Phil. Trans.* for 1772, p. 476. The needles were a foot long, and the ends of the axes, which were made of gold alloyed with copper, rested on friction wheels 4 inches in diameter.

A complicated dipping needle by Dr Lorimer, for determining the dip at sea, is described in the *Phil. Trans.*, 1775, p. 79.

The dipping needle used by the Royal Society, and regarded as a model for instruments of this kind, is described by Mr Cavendish in the *Phil. Trans.* for 1776, p. 375. The axis of the needle rested on agate planes, and there was a contrivance, as in Gilbert's instrument above described, for raising and turning the needle upon the same part of the planes.

In one of M. Gambey's dipping needles, executed at Paris, and intended to be used at St Petersburg, the axis, instead of being cylindrical, is a knife edge, as in delicate balances. This edge is placed exactly in the centre of gravity of the whole compound needles, and is so fixed, that when the needle dips 71° (as at St Petersburg), the edge rests perpendicularly on two agate plates. Such dipping needles, made for particular values of the dip, are admirably fitted for measuring minute variations of inclination, whether they be diurnal, menstrual, or annual.

Sect. XI.—*Account of Dr Scoresby's Magnetometer for measuring the Dip of the Needle.*

Scoresby's magnetometer.

This ingenious instrument consists of a horizontal table, or leaf, a part of which, made of brass, may be set by a screw and pinion at any angle to the horizon; and this leaf contains near one of its edges two rings, through which we can pass a bar of soft unmagnetic iron, so that its length is perpendicular to the axis or line round which the brass leaf moves. On the same side of the leaf, and concentric with the above axis, is a graduated circle divided into 360°, so that when the bar of iron is put into the rings of the brass

Description of Magnetical Instruments.

leaf, the bar coincides, in every position of the leaf, with a radius of the divided circle; and it is therefore easy to measure the angle which the bar makes with the horizon, whatever be the position of the leaf on which it rests. A compass is placed on the fixed leaf of the table, which by means of levels may be adjusted to a horizontal position.

Now it was ascertained by Mr Barlow, that when a bar of iron is in the magnetic equator, it loses all its power of affecting the needle of a compass placed near it. Dr Scoresby therefore elevates the brass leaf of the table, and consequently the bar of iron, till it ceases to act on the needle; and the complement of the inclination of the bar, as measured by the graduated circle, is the dip required. This method is of course not equal in accuracy to that described above, or to the methods of Mayer and Dr Lloyd, explained in subsequent sections. It may be used, however, most advantageously in obtaining an approximate measure of the dip when more delicate instruments cannot be procured. See the *Edinburgh Transactions*, vol. ix., p. 247; and the *Edinburgh Philosophical Journal*, vol. ix., p. 41.

SECT. XII.—*Description of Sir William Snow Harris's Hydrostatic Magnetometer.*

Snow Harris's hydrostatic magnetometers.

This ingenious instrument is of such universal application in exhibiting the elementary phenomena of magnetism, and in measuring magnetic forces, that an accurate description of it, both as an instrument of illustration and research, cannot fail to be acceptable to our readers. With the kind permission of its author, we have availed ourselves of the accurate description of it given in the 2d part of his *Rudimentary Magnetism.*

"A light grooved wheel, W (fig. 103), about 2 inches in diameter, being accurately poised on a firm axis *m n*, is mounted on the smooth circumferences of two similar wheels *mw, nw'*. The extremities of the axis *m n* are turned down to fine long pivots, and whilst resting on the friction-wheels *mw, nw'*, pass out at *mn*, between other small check-wheels, two at each extremity of the axis, so that the wheel W cannot fall to either side: great freedom of motion is thus obtained. These friction and check wheels are set on points or pivots in light frames of brass, and the whole is supported on short pillars screwed to a horizontal plate or stage AB (fig. 104). The stage is sustained on a vertical column AE, fixed to an elliptical base of mahogany E, supported on three levelling screws.

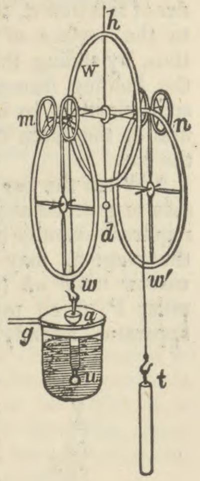

Fig. 103.

"There is a short pin *h*, fig. 103, fixed in the circumference of the wheel W, to receive an index of light reed, cut to a point, and moveable over a graduated arc MN, placed behind the wheel, as represented in fig. 104: the weight of this index is balanced by a small globular mass *d*, moveable on a screw in the opposite point of the circumference; so that the wheel alone with the index would rest in any position, or nearly so. The arc MN is a quadrant divided into 180 parts,—90 in the direction OM, and 90 in the direction ON, the centre O being marked zero. Two fine holes are drilled through the wheel, one on each side of the point *h*, for receiving and securing two silk lines, *w, w'*: these lines pass over the circumference on opposite arms of the wheel, and terminate in small hooks, *t* and *w*. A cylinder of soft iron *t*, or a small magnet, rather less than 2 inches in length and $\frac{1}{4}$th of an inch in diameter, is suspended by a silk loop from one of these lines *w*, and a cylindrical counterpoise of wood, *au*, weighted at *u*, and partly immersed in water, is hung in like manner from the other line, *w*. The weights, and altitude of the water, and of the vessel V containing it, are so adjusted, that when the whole system is in equilibrio, the index is at zero of the arc MN. With a view to a perfect adjustment of the index, the water-vessel V is supported in a ring of brass at the extremity of a rod *g*, moveable in a tube *k* (fig. 104): this tube is attached to a sliding piece *kh*, acted on by a milled head at *h* and a screw within the cylinder, which is fixed to the stage AB,—so that the water-vessel may be easily raised or depressed by a small quantity, and thus the index be regulated to zero of the arc with the greatest precision; for it is evident, by the construction of the instrument, that the position of the index will depend on the greater or less immersion of the cylindrical counterpoise *au*, the weight of which being once adjusted to a given line of immersion, and a given position of the wheel W and index O, any elevation or depression of the water-vessel V must necessarily move the wheel. The counterpoise *au* is about $1\frac{1}{2}$ inch in length and full ·3 of an inch in diameter: a small ball of lead is attached to its lowest part, in order to give it a sufficient immersion, and at the same time balance the iron cylinder *t* when the float is about half immersed in the water. With a view to a final regulation of the weight, a small hemispherical cup *a* is fixed on the head of the counterpoise for the reception of any further small weights required. This counterpoise is accurately turned out of fine-grained mahogany, and is freed from grease or varnish of

Description of Magnetical Instruments.

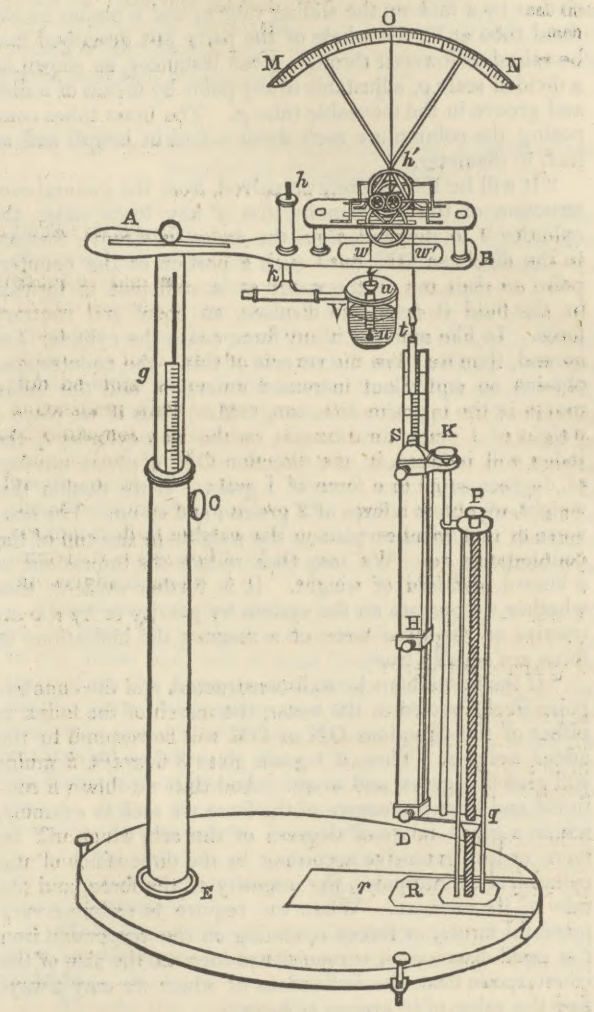

Fig. 104.

Description of Magnetical Instruments.

any kind, so as to admit of its becoming easily wetted in the water.

"The column AE supporting the stage AB consists of two tubes of brass, one *g* moveable within the other EC, so that by a rack on the sliding tube *g*, and a pinion on the fixed tube at C, the whole of the parts just described may be raised or lowered through given distances, as shown by a divided scale *g*, adjustable to any point by means of a slide and groove in the moveable tube *g*. The brass tubes composing the column are each about a foot in length and an inch in diameter.

"It will be immediately perceived, from the general construction of this instrument, that if any force cause the cylinder *t* to descend, then the index will move forward in the direction ON, until such a portion of the counterpoise *au* rises out of the water as is sufficient to furnish, in the fluid it ceases to displace, an equal and contrary force. In like manner, if any force cause the cylinder *t* to ascend, then we have the reverse of this,—the counterpoise obtains an equivalent increased emersion, and the index moves in the opposite direction, OM. Thus if we place a weight of 1 grain, for example, on the iron cylinder *t*, the index will indicate, in the direction ON, a given number of degrees equal to a force of 1 grain. If we double this weight, we obtain a force of 2 grains; and so on. The converse of this arises on placing the weights in the cup of the counterpoise *au*. We may thus reduce the indications to a known standard of weight. It is further evident, that whether we operate on the system by gravity or by the attractive or repulsive force of a magnet, the indications of force are equally true.

"If the instrument be well constructed, and the counterpoise freely wetted in the water, the march of the index in either of the directions ON or OM will correspond to the added weights. Thus, if 1 grain gives 3 degrees, 2 grains will give 6 degrees, and so on. And thus we obtain a continual and known measure of the force we seek to examine, within a given range of degrees of the arc, which will be more or less extensive according to the dimensions of the cylindrical counterpoise, the intensity of the force, and the rate of its increase. When we require to examine very powerful forces, or forces operating on the suspended iron *t* at small distances, it is requisite to increase the size of the counterpoise float, the indications of which we may always find the value of in grains, as before.

"Previously to suspending the cylindrical counterpoise *au*, the iron cylinder *t* should be placed in equilibrio on the wheel W, with an equal and opposite weight, as previously determined by an accurate scale-beam, in order to observe if, when loaded with the whole, the wheel W and index are indifferent as to position on any part of the arc, or nearly so. The instrument will be sufficiently delicate, if, when loaded in this way with 350 grains, it is set in motion by something more than half a grain added to either side.

"In order to retain the wheel W (figs. 103 and 104), in its position at the time of removing either of the suspended bodies, a small brass prong is inserted at h' into the arms of the circular segment MN, so as to inclose the pin h' carrying the index: the wheel is thus prevented from falling to either side.

"The forces requiring to be measured are brought to operate on the suspended cylinder *t* through the medium of induction on soft iron, or by a magnetic bar placed immediately under it, either vertically or horizontally. In the vertical arrangement, shown in fig. 104, the magnet or iron is fixed against a graduated scale S, by which the distance between the attracting surfaces or bodies is estimated. This scale, together with the magnet H, is secured by light bands of brass, united by a rod DK. The lower band and rod D are both fixed to a stage D, moveable between guide-pieces, and acted on through a nut at *q* by a vertical screw P*q*, about 6 inches in length and $\frac{3}{8}$ths of an inch in diameter; so that the whole may be raised or depressed, and hence the suspended cylinder and magnet placed at any required distance apart. The regulation of this important element in the operation of magnetic forces is hence provided for in two ways, viz., by the rack at *g* and the milled head at P, either of which may be employed, as found most convenient. The scale S is of boxwood, 1 foot in length, $\frac{3}{4}$ths of an inch wide, and $\frac{1}{4}$th of an inch thick: it is divided into inches, subdivided into tenths and twentieths of an inch. About 6 inches of the upper part is divided in this way, viz., 3 inches on each side of a central division, which is marked zero; the rest of the piece extends to the stage D. The magnetic bar H is tied to the scale by compressing screws and simple brass bands, either fixed, as at D and K, or moveable, as at H. This adjusting apparatus is secured to a stout brass plate R, fitted by a dovetail into a sliding piece *r*, forming part of the mahogany stand E, so that it may be removed at pleasure. The brass bands and frames at D, H, K, are sufficiently capacious to inclose two bars together if required, the superabundant space being filled when only one magnet is employed, either by a bar of wood or small wedge pieces in the brass frames.

Description of Magnetical Instruments.

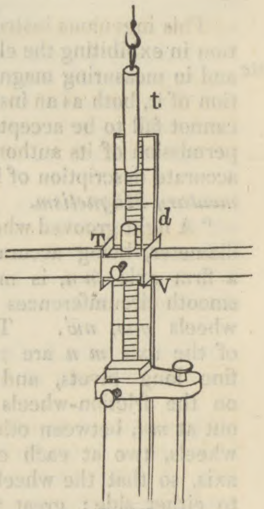

Fig. 105.

"When we require to examine the forces in different points of a moderate-sized magnetic bar, the bar is laid in a small frame-piece TV (fig. 105), temporarily fixed by a compressing screw to the divided scale S, in the way already described; the force on the suspended cylinder *t* being caused to operate through a small cylinder of soft iron *d*, accurately fitted to the surface of the bar; and thus, by sliding the bar along in the holding frame, we may get, approximately, by induction on the iron *d*, the force of any point in the bar.

"When the bar is of considerable magnitude and weight, or we require to examine inductive forces, the magnets may be placed on a narrow table *ab* (fig. 106), supported on a central square pillar P, fitted to the frame-pieces KP of the adjusting apparatus already described, so that the whole may be raised or depressed through any given distance. In this case the divided scale S (fig. 106), which measures the distance *a* between the attracting or repelling surfaces, is a detached piece fixed against one of the perpendicular sides of a right-angled triangle, so as to be anywhere placed upright on the bar: the table *ab* also has a divided scale *s*, moveable in a wide groove through its centre,

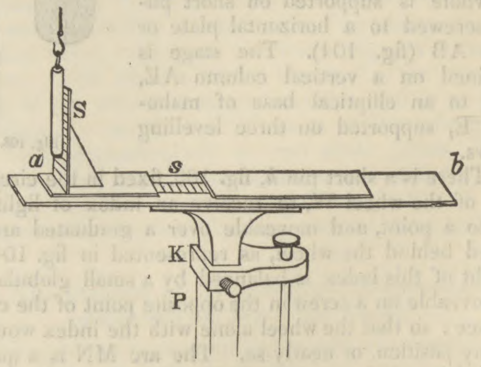

Fig. 106.

Description of Magnetical Instruments.

by which any distance *s* between magnetic masses may be also shown. When the bars are very ponderous, two supports are required, one at each end of the table *ab*.

"Inductive forces are examined vertically by fixing the masses by compressing bands *s* against the scale S, as represented in the annexed fig. 107, and of which we may have, if requisite, two or three in succession.

"These arrangements put us in a position to note readily and simultaneously all relative distances and forces under a great variety of magnetic and apparently complicated conditions. In the arrangement (fig. 107), for example, we may fix a mass of iron S, at successive distances S, N from a magnet H, and yet preserve the distance *ab* at which the induced force operates constant, either by the rack and pinion C, or the milled head and screw PR (fig. 104), and thus arrive at a measure of the inductive force on the intermediate mass S."

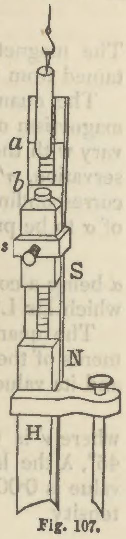

Fig. 107.

SECT. XIII.—*Account of Daniel Bernoulli's Dipping Needle.*

Bernoulli's dipping needle.

If AB is a needle, C its axis, a light graduated circle DEFG is fixed upon it, so as to have its centre coincident with C, and a light index D is fixed to the axis C, so as to turn tightly upon it. Let the needle be magnetized previous to the putting on of the index D, and nicely balanced. The index will obviously destroy the equilibrium, and will always point perpendicularly to the horizon, if the needle has been properly balanced. As this degree of accuracy, however, cannot be expected, let the index D be set to different parts of the circle EFG, and let the inclination taken by the needle before it is magnetized be noted down, corresponding to the different positions of the index. When the index points to 50°, for example, let the inclination of the needle be 46°. If we now observe that the needle is still inclined 46°, when the index is at 50°, after it is magnetized, then 46° is the true magnetic dip at that place, as the magnetism which it has received does not alter the position which it assumes from its gravity alone.

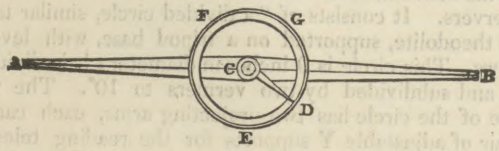

Fig. 108.

As it is easy to obtain a rude estimate of the dip at any place, let the index D be set accordingly, and if the needle does not now show the estimated dip, the position of the index must be changed, and the inclination or dip of the needle again noted. Observe if this second position of the index, and the second measure of the dip, form a corresponding pair of numbers, such as have been written down. If they do, we have got the true dip; but if they do not, another position of the index must be tried. If the coincidence of this new pair of numbers is greater or less than that of the former pair, we shall learn whether the position of the index is to be altered in the same direction as before, or in an opposite one.

Dr Robison made several observations with a dipping needle of this construction, which was executed by a person totally unacquainted with the making of such instruments. He measured the dip with it at Cronstadt, at New York, and Scarborough, and the result never deviated more than 1½° from that obtained by the present dipping needles. He tried it also in a rough sea in Leith Roads, and he found it not inferior either in accuracy or despatch to the most elaborate instruments.

Description of Magnetical Instruments.

SECT. XIV.—*Account of Mayer's Dipping Needle, as constructed for General Sabine.*

Mayer's dipping needle.

The method of observing the dip employed by the celebrated Tobias Mayer,[1] consists in separating the centres of motion and of gravity of the needle, and in deducing the true dip from the apparent dip thus obtained.

The needle executed for General Sabine on this principle was a parallelopiped 11½ inches long, $\frac{4}{10}$ths broad, $\frac{1}{20}$th of an inch thick. The ends were rounded, and a line drawn on the face of the needle through its centre to its extremities, for the purpose of an index. The needle turned upon a cylindrical axis of bell-metal, terminated by cylinders of the smallest diameter, that could support the needle without bending. These small cylindrical ends rested upon agate planes. The needle was raised from or lowered to its support by Y's, which insured that the same parts of the small cylinders rested on the agate planes in each observation.

A small steel screw was inserted in a female screw, tapped on the lower edge of the needle, in a direction perpendicular to the index line, and a small brass sphere was made to traverse on this screw, so that the centre of gravity of the needle, screw, and sphere may be made to fall more or less below the axis of motion, and thus give the needle a momentum auxiliary to that of magnetism, in overcoming the inequalities of workmanship in the axis, or in the agate planes. Hence the position which the needle assumes, under these circumstances, is not that of the true dipping needle; but, by a simple formula, the true dip may be deduced from four observations, when conducted in the following manner:—

1. Place the needle in the magnetic meridian, and observe the angle which it makes with the vertical. Call this angle M.

2. Reverse the position of the axis on its supports, so that the edge of the needle, which was uppermost in the preceding observation, is now lowermost, and observe again the angle which the needle makes with the vertical, and call this *m*. Let the poles of the needle be now reversed by means of a powerful magnet, and when it is replaced, make the same observations which have been already described, and call the angles thus obtained N, *n*. Then calling the sum of the tangents of M and $m = \text{A}$; the difference of the same tangents $= a$; the sum of the tangents N, $n = \text{B}$, and their difference $= b$. Then the dip Δ may be obtained from the following formula:—

$$\text{cotan}\ \Delta = \tfrac{1}{2}\left(\frac{\text{A} \times b}{a + b} + \frac{a \times \text{B}}{a + b}\right).$$

In order to insure the perfect horizontality of the agate planes, or of the axis of the needle which rests upon them, a spirit level attached to a circular brass plate, with adjustments to bring the level parallel to the plate, was placed upon the planes themselves. The errors of the level were shown by placing the plate in various positions, and the errors of the planes by turning the whole instrument on its horizontal centre.

If we observe the inclination of the dipping needle to the horizon in two different positions, so that the planes in

---

[1] *Göttingen Transactions*, 1814.

Description of Magnetical Instruments.

which it moves are at right angles to one another, the true dip may be obtained from the formula:—

$$\text{cotang}^2 \Delta = \text{cotang}^2 \text{I} + \text{cotang}^2 \text{I}';$$

the inclination in the two rectangular azimuths being I and I′. The dip may be thus very accurately obtained from the mean of a number of observations in different azimuths.

SECT. XV.—*Account of Dr Lloyd's method of observing the Dip and the Magnetic Intensity at the same time, and with the same Instrument.*

Dr Lloyd's method of observing the dip, &c.

The ordinary dipping needle employed by Dr Lloyd, is supported on an axis which is supposed to pass accurately through its centre of gravity, and hence the position which it takes in the magnetic meridian is the direction of the magnetic force. If one of the arms of the needle, however, is loaded with a weight, the needle will assume a new position of equilibrium under the united influence of gravity and of terrestrial magnetism. By means of the inclination of the needle thus obtained, and the amount of the added weight, the dip of the needle, and the magnetic intensity, may be obtained by the following formulæ:—Let μ, ν be the statical moments of two small weights attached in succession to the southern arm of the needle at fixed distances from its centre, and let ζ be the inclination obtained with the weight μ, and θ that obtained with ν. Then

$$\mu \cos \zeta = \varphi \sigma \sin (\delta - \zeta),$$
$$\nu \cos \theta = \varphi \sigma \sin (\delta - \theta);$$

the dip being denoted by δ, and the magnetic intensity by φ, and σ being a constant depending on the distribution of magnetism in the needle itself. Hence from the inclinations ζ and θ observed in the usual manner, and the ratio of the moments μ and ν, the dip and the relative magnetic intensity will be obtained at the several places of observation.

The most advantageous way of applying the preceding method, Dr Lloyd considers to be this: He observes the position of the needle, *first*, when *unloaded*; and, *secondly*, when loaded with a weight sufficient to bring it into a position nearly perpendicular to the line of the dip.

Now if $\mu = 0$, we shall have $\zeta = \delta$, or the inclination first observed becomes equal to the dip, when there is no weight acting with or against the directive force. This condition, however, is never accurately fulfilled; for, from the imperfect coincidence of the centre of gravity of the needle with the axis, the weight of the needle itself is sufficient to deflect it from the true line of the dip. We must therefore regard ζ as the approximate value of the dip, and compute the correction for reducing it to its exact value.

For this purpose put $\rho = \frac{\mu}{\nu}$, and dividing the first of the above equations by the second we have

$$\rho \frac{\cos \zeta}{\cos \theta} = \frac{\sin (\delta - \zeta)}{\sin (\delta - \theta)}.$$

Then if we make $\delta = \zeta + \epsilon$, the second term of the preceding equation becomes $\frac{\sin \epsilon}{\sin \zeta - \theta}$ nearly, since ϵ is a very small quantity, and we have

$$\sin \epsilon = \rho \frac{\cos \zeta}{\cos \theta} \sin (\zeta - \theta).$$

Hence we may find the dip by means of these two equations, and we may deduce the correction for an imperfect balance of the needle from the two observed inclinations without reversing the poles of the needle, as in the method of Tobias Mayer.

The value of the coefficient ρ in the last equation is given in the following formula:—

$$\rho = \frac{\cos \theta \sin (\delta - \zeta)}{\cos \zeta \sin (\delta - \theta)}.$$

The magnetic intensity at different stations may be obtained from the dip by the second equation.

The quantity σ, being the statical amount of the free magnetism of the needle, or the *magnetic moment*, must vary with the temperature. If τ is the temperature of observation, τ' a certain standard temperature, and σ' the corresponding value of σ, then if we suppose the changes of σ to be proportioned to those of τ, we have

$$\sigma = \sigma' (\text{I} - a) (\tau - \tau');$$

a being a constant to be determined by observation, and which Dr Lloyd found to be 0·00016.

The quantity ν is the sum (or difference) of the moments of the weight of the needle and of the added weight, and its value is

$$\nu = \nu' (1 - e \cos 2\lambda)$$

where ν' is the value of ν corresponding to the latitude of 45°, λ the latitude of the place, and e a constant, whose value is 0·002588. Hence we obtain for the magnetic intensity

$$\varphi = \frac{\nu \cos \theta}{\sigma' \sin (\delta - \theta)} + \frac{1 - e \cos 2 \lambda}{1 - a (\tau - \tau')},$$

an expression peculiarly adapted for logarithmic computation. (See *Memoirs of the Royal Irish Academy* 1835.)

SECT. XVI.—*Description of Dr Lloyd's Theodolite Magnetometer.*

Dr Lloyd's theodolite magnetometer.

This instrument is intended for the use of travelling observers. It consists of "a divided circle, similar to that of a theodolite, supported on a tripod base, with levelling screws. This circle is 9 inches in diameter; it is divided to 10′, and subdivided by two verniers to 10″. The upper plate of the circle has two projecting arms, each carrying a pair of adjustable Y supports for the reading telescope, at a distance of 6 inches from the centre. The telescope rests in these supports on a transit axis, which is rendered horizontal by the help of a riding level. The aperture of the object glass is $\frac{8}{10}$ths of an inch; a glass scale, divided to the $\frac{1}{400}$th of an inch, is fixed in its focus; and the eye tube is made to move across the scale in a dovetail slide.

"The magnets are hollow cylinders, each furnished as a collimator with an achromatic lens, and a fine line cut on glass in its focus. There are four such magnets: two of them being $3\frac{2}{3}$d inches long and $\frac{1}{2}$ an inch in exterior diameter, and two 3 inches long and $\frac{3}{8}$ths of an inch in exterior diameter. The larger magnets are furnished with a Y stirrup, in which they may be inverted; the small magnets have the ordinary tubular stirrup, with a suspension pin and screw socket. A hollow brass cylinder, of the same dimensions as the larger magnets, and carrying a small hollow cylindrical magnet within, serves to determine the amount of torsion of the suspension thread; it is likewise fitted up as a collimator.

"There are two boxes, within which the magnets are to be suspended. That belonging to the smaller magnets is a rectangular box of copper, closed by mahogany sliding sides, and having a circular aperture at each end filled with parallel glass. It is $3\frac{1}{2}$ inches long, $1\frac{1}{2}$ inch wide, and 1 inch deep internally; and the thickness of the metal is $\frac{1}{4}$th of an inch, so that it may act powerfully as a damper. A suspension tube of glass, 8 inches long, is screwed into an aperture in the top of the box; and is furnished with a graduated torsion cap at top, and a sliding suspension-pin. This box is made to fit on the centre of the upper plate of the circle, and is capable of removal at pleasure. The box employed with the larger magnets is of wood, and of the same form as the copper box, but somewhat larger. It is detached from the instrument, but may rest on the same

Description of Magnetical Instruments.

stand. A small wooden piece with a mirror serves to illuminate the magnet collimator, either from above or from the side, according as the light of day, or that of a lamp or candle, is employed.

"The measuring rod employed in deflection experiments is a compound bar of gun-metal, formed of two bars, the lower of which has its surface horizontal, and the upper vertical. It is 3 feet in length, and is graduated on its vertical surface. It is placed upon the upper plate of the circle, beneath the box, and at right angles to its longer sides; and it is so fixed that it may be removed with ease, and replaced exactly in the same position. The support of the deflecting magnet slides upon the upper bar, and is furnished with a vernier, by means of which the distance of the two magnets may be determined with accuracy and ease."

SECT. XVII.—*Description of Dr Lloyd's Instrument for Measuring the Inclination and its Changes.*

Dr Lloyd's inclination instrument.

In 1842 Dr Lloyd communicated to the Royal Irish Academy an account of a "new magnetical instrument for the measurement of the inclination and its changes." In consequence of the sources of error inherent in every direct process of determining the third magnetic element, indirect methods of determining the inclination were proposed in Germany—one by Professors Gauss and Weber, and the other by Dr Sartorius von Walterhausen. Dr Lloyd's method bears a close analogy in principle to the former, but it differs from it both as to the means employed, and in the end in view,—his main object being to determine the inclination-changes.

"If a soft-iron bar, perfectly devoid of magnetic polarity, be held in a vertical position, it immediately becomes a temporary magnet under the inducing action of the earth's magnetic force, the lower extremity becoming a north pole, and the upper a south pole. Accordingly, if a freely-suspended horizontal magnet, whose dimensions are small in comparison with those of the bar, be situated near, in a plane passing through one of these poles, it will be deflected from the magnetic meridian. The deflecting force is the induced force of the bar, which may be regarded as proportional to the energy of the inducing cause, *i. e.*, to the *vertical component* of the earth's force; while the counteracting force is the *horizontal component* of the same force, acting directly on the magnet itself, to bring it back to the magnetic meridian. Thus the magnet will take up a position of equilibrium, under the action of these opposing forces; and this position will serve to determine the ratio which subsists between them. When the right line connecting the centre of the horizontal magnet and the acting pole of the bar, is perpendicular to the magnetic meridian, the tangent of the angle of deflection will measure the ratio of the two forces, and will therefore be proportional to the *tangent of the magnetic inclination*. Accordingly, by observing the changes of position of the horizontal magnet, so circumstanced, we can infer those of the inclination itself.

"But the iron bar may have (and generally will have) a certain portion of *permanent* magnetism, which will concur with the induced magnetism in producing the deflection; and it becomes necessary to institute the observations in such a manner, as to be able to eliminate the effects of this extraneous cause. For this purpose we have only to invert the bar, so that the acting pole, which was uppermost in one part of the observation, shall be lowermost in the other. The induced polarity will, under these circumstances, be opposite in the two cases; and the acting force will in one case be the *sum* of the *induced* and *permanent* forces, and in the other their *difference*. The following is the construction of the apparatus:—

Description of Magnetical Instruments.

"The magnet is cylindrical; its length is 3 inches, and diameter $\frac{1}{4}$th of an inch. A mirror is attached to the stirrup by which it is suspended, by means of which the varying position of the magnet may be observed with a telescope at a distance, after the method of Gauss. This mirror is of course vertical; and it has a motion round a vertical axis, by means of which it may be adjusted to any desired position of the observing telescope. The mirror is circular, and is $\frac{3}{4}$ths of an inch in diameter. The moveable part of the stirrup to which it is attached has the form of a cross; and it is rendered vertical by means of three screws, near the extremities of three of the arms of the cross, the heads of which project and hold it. The mirror is maintained in contact with these heads by springs at the backs.

"The box is octagonal; the interval between the opposite sides is 4 inches, and that between the top and bottom 2 inches. The top and bottom, and the connecting pillars, are formed of gun-metal; the eight sides are closed by moveable pieces, three of which are of glass, and the rest of ebony. To the top of the box is attached an upright tube of glass, 8 inches in length, which incloses the suspension thread. The suspension apparatus at the top of the tube is of the usual construction; the circular piece to which it is attached has a movement of rotation, and its outer surface is graduated to 5°, for the purpose of determining the effect of torsion of the suspension thread.

"The base of the instrument is a circle of gun-metal, 6 inches in diameter, graduated on the edge. The box is connected with this circle by a short conical stem, forming the axis of a second plate, which revolves upon the fixed one. This moveable plate carries two verniers, by which the angle of rotation may be read off to minutes. Two tubular arms, slightly inclined to one another, are attached to this plate; and their other extremities are connected by a cross-piece, which carries a short scale at a distance of 18 inches from the mirror. This part of the apparatus is employed in determining the total angles of deflection.

"The soft-iron bar is a cylinder, 12 inches long and $\frac{3}{4}$ths of an inch in diameter. One of its extremities is inclosed in a hollow cylinder of brass, connected with a horizontal pivot which revolves in a fixed socket. The axis of this pivot being in the line passing through the centre of the suspended magnet, and perpendicular to the magnetic meridian, it is obvious that the bar has a movement of rotation in the plane of the magnetic meridian itself. The distance of the axis of the bar from the centre of the magnet is about 5 inches; and it is so placed that the induced pole is in the direction of the axis of the pivot, and thus remains fixed during the movement of the bar.

"The changes of position of the suspended magnet are observed at a distance by means of a fixed telescope and scale. The scale, whose divisions are reflected by the mirror, is attached above the telescope to the support near the eye-end."

SECT. XVIII.—*Description of Mr Fox's Dipping Needle Deflector, for measuring the Variation and Dip of the Needle, and the Magnetic Intensity.*

Mr Fox's deflector.

This ingenious instrument, for ascertaining the variation, dip, and intensity of terrestrial magnetism, was pretty extensively used by Mr Fox in different parts of the United Kingdom. The results have been published both in a table and in a chart in an extract from the *Report of the Royal Cornwall Polytechnic Society* for 1835.

The deflector is shown in figs. 109 and 110, where A is a cylindrical box of brass fixed vertically in the stem B and horizontal plate C, all of which can be turned round on their common axis D, ground into the centre of a tripod,

Description of Magnetical Instruments.

two of whose legs are shown at E and F. The graduated circle in C is subdivided by a vernier and tangent screw G, levels being placed at right angles to each other for adjustment. The needle *ns*, with a small grooved wheel *a* fixed on its axis, is supported by the concentric disc *c*, and a bracket *e* attached to the disc, the axis of the needle moving in jewelled holes. The disc *c* is accurately fixed into the back of the box, and may be turned round with the bracket on its axis by means of knobs on its back, shown in fig. 110. By this contrivance the bracket may be moved round to any convenient position, so as not to interfere with the dip of the needle in any latitude.

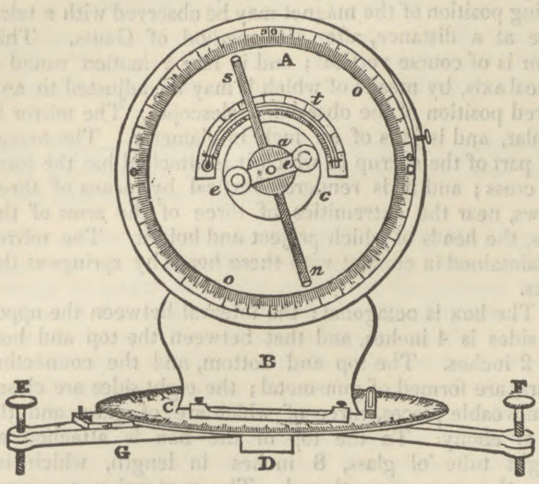

Fig. 109.

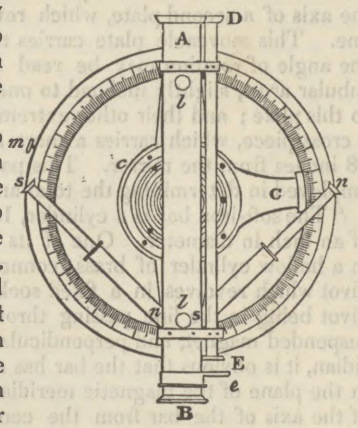

Fig. 110.

A socket, attached to a brass spring, when pressed forward by the screw *m*, is intended to confine the ends of the needle when not in use. There are two parallel graduated rings, one ot which is a little within the outer surface of the dipping needle, as shown at *oo* fig. 109; the other ring, supposed to be removed in the figure, is immediately under the glass, its object being to direct the sight, and enable the observer to subdivide the degrees on the inner circle. A thermometer is shown at *t*. The back of the dipping-needle box is shown in fig. 111; the back of the moveable central disc is grooved, and a brass rod is drawn over the grooved surface in order to make the needle vibrate.

A telescope AB, having cross wires, is capable of being moved in a vertical plane in any direction, by means of a concentric ring *c*, grooved into another concentric ring attached to the back of the instrument, and furnished with a flanch. An arm C, at right angles to the telescope, has a vernier for subdividing the graduated circle on the back of the box. A small tube DE for solar observations, is fixed parallel to the telescope. This tube has a convex glass at D, whose focal length is rather longer than the tube, and there is a plane glass at E, with a small circular spot on it, which forms, with the concentrated light of the magnifying glass, a distinct annular image on an ivory or plaster of Paris surface at *e*. Magnetized steel bars are placed in the brass tubes *ns*, *sn*. Their positition, as well as that of the telescope, when not in use, is shown in fig. 111, the *n* and *s* poles of the magnet being brought near the *s* and *n* poles of the dipping needle in the box, in order to induce a uniformity in their relative states of magnetic intensity. Holes *l*, *l* are made in the tube of the telescope, to allow the magnets to be passed through it, and screwed into the arms which hold the telescope. This is shown at *n* and *s* fig. 110, which represents a side view of the box, and the places of the magnet when employed for ascertaining the intensity. Two brass screws fix the ring and glass cover, over the face of the instrument, are shown at *a*, *a*. Fig. 112 represents a grooved wheel fixed in the axis of the needle *a* (fig. 109), with a fine silk thread, having hooks at each end, passing over the wheel in the grooves.

Description of Magnetical Instruments.

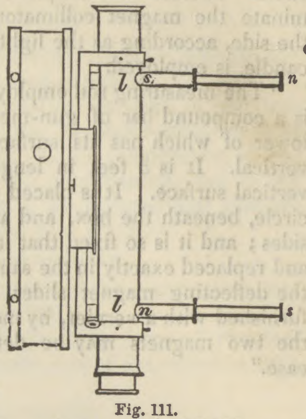

Fig. 111.

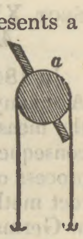

Fig. 112.

The following rules for using the instrument are given by Mr Fox:—

To observe the Magnetic Variation.—Ascertain the true meridian by any of the usual methods; the small tube being used for solar observations, and the telescope for observations at night. Note the angle cut by the nonius on the circular plate C. If the plate be turned round 90° from that point, the face of the instrument, or rather the plane in which the needle moves, being parallel to that of the tubes, will be at right angles to the plane of the true meridian. The deflecting tubes *n*, *s* having been removed from the back, turn the instrument round *gradually*, so that the needle may become *perfectly vertical* after vibration; friction having been employed several times at the back of the central disc. Fig. 110.

The face of the instrument will then be at right angles to the plane of the magnetic meridian; and the angle described on the circular plate will give the variation from the true meridian. The face of the instrument, however, should always be turned round to the opposite quarter, till the needle again becomes vertical, which will either confirm or correct the preceding experiment, by taking half the differenee between the two observations.

To ascertain the Dip.—The face of the instrument having been made to coincide with the *plane* of the magnetic meridian, suppose it to be at first turned towards the east; note the exact dip at *both* ends of the needle after vibration, as before described (this percaution should, in every case, be carefully attended to, and repeated several times); then turn the face of it toward the west, placing it in the same plane, and observe and note as before; the mean of these observations will give the dip.

To correct the observed Dip.—The instrument being still in the magnetic plane, and fixed in that position by means of the lever or clamp connected with the nonius, screw on one of the deflectors *n*, *s* at right angles to the tube as shown in fig. 111, so as to repel or deflect the end of the needle which is nearest to it; then, if the observed dip was 69° 45′, move the deflector a certain number of degrees from 69° 45′, as shown by the nonius *c*; say 50° to the right of the dip, when the needle will be repelled in the opposite direction: suppose the mean angle at *both* poles of the needle, after frequent vibrations, to be 54° 33′
then move the tube 50° to the left of the dip, when the needle will be repelled in the contrary direction: suppose it to stand at . . 84° 47′

Mean, . 69° 40′

Description of Magnetical Instruments.

If the face of the instrument, whilst making these observations, should be towards the east; turn it round towards the west, adjusting it in the same plane, and repeat the observation; if the mean result should be . . . 69° 46′
the mean or corrected dip will be . . . . 69° 43′

Similar observations may be multiplied at pleasure, by varying the angles of the deflector from the observed dip; and by thus taking the mean of many observations, the true dip may be obtained with a great degree of precision.

To find the relative Intensity of the Terrestrial Magnetism.—The instrument being still in the plane of the magnetic meridian, screw the deflectors (or one of them) into the arms at the back of the instrument, as shown in fig. 110, and cause the latter to coincide with the direction of the dip, when the needle will be repelled from it; mark the angle to which the needle points at both ends (after repeated vibrations as before described), then cause the needle to swing back to the other side of the dip (one of the deflectors being temporarily removed for this purpose), and note its place as before: half the sum of the angles to which the needle is thus deflected (or rather of their sines) will represent the relative force of the terrestrial magnetism, at different places, on a needle thus circumstanced. It is desirable that the observations should be made with the face of the instrument turned towards the east as well as towards the west, and likewise only one deflector may be used as well as both of them; in order to vary and multiply the observations for the purpose of correction.

If the angle of deflection at a second place of observation should be greater or less than at the first, the force of the earth's magnetism will be inferior or superior to the latter, as represented by the different angles

The amount of any such difference may, when required, be represented by weights:—For this purpose, the glass which protects the face of the instrument should be removed, and the silk thread placed on the grooved wheel, as shown in fig. 112. The minute weights required to be suspended to one of the hooks, in order to bring the needle to some given angle from the actual dip, will indicate the relative magnetic intensity at different stations. Suppose, for example, that at a given place the observed dip is 70°, and that at a second place, in a lower latitude, it is 45°; adjust the deflector as before described, so as to coincide with the dip of the needle at the place of observation, whatever it may be. Assume that the needle is repelled 70° from the dip of 70° at the first station, and 80° from the dip of 45° at the second station; it will show that the terrestrial magnetic intensity is greater at the former than at the latter. The weights required to be suspended to one of the hooks, in order to bring the needle to its original position of 71° from the dip (if that be taken as the standard), will indicate the difference of intensity. Thus, for instance, if five-tenths of a grain be required to bring the needle from the angular distance of 80° to that of 70° from the dip at the second station, this weight will indicate the *difference* of the magnetic intensity of the earth at the *two* stations, acting on the needle in question, when at an angle of 70° from the natural dip.

The ratio of this difference to the whole force of the terrestrial magnetism so acting, may be ascertained by moving the deflectors to the angle of 70° from the dip (because the needle is assumed to have been deflected to this angle at the first station); the needle will then be repelled to the opposite side of the dip, and the weight required to counteract the deflection sufficiently to bring it back to the dip, will represent the whole influence of the earth's magnetism, at the first station on the needle, whilst at the angle of 70° from the dip. This will be evident, when it is considered that the angle between the needle and deflectors is in both instances the same; it being coerced contrary to the repelling force of the deflectors, in one case by the earth's magnetism, and in the other by the weights, to the *dip or line of quiescence.* The earth's magnetic force acting on the needle so deflected, will therefore be equal to the gravity of the weights. If 3·34 grains be the weights required, and five-tenths of a grain equal to the difference between the two stations, the terrestrial magnetic intensity will be in the ratio of $3{\cdot}34 - {\cdot}5 = 2{\cdot}84$, at the second station, to 3·34 at the first station.

Description of Magnetical Instruments.

From the observations which have been already made with the dipping-needle deflector, furnished with a needle less than six inches long, there is good reason to believe that it will clearly indicate a difference of intensity at places situate at less than one-half a degree of latitude from each other.

Observations on the magnetic intensity and dip may likewise be made *without the deflectors*, by means of the weights only, suspended from the silk thread, shown in fig. 112. This method is too obvious to require a minute description, the weights in this case being used to produce deflection from the dip at any place, instead of the magnetic deflectors; the weights required to cause a given amount of deflection being taken as the relative measure of the magnetic intensity at the place of observation. Thus, in the case before supposed, 3·34 grains would produce a mean deflection of 70° from the dip at the first station, and only 2·84 grains would do so at the second station.

SECT. XIX.—*Account of Lebaillif's Sideroscope.*

Lebaillif's sideroscope.

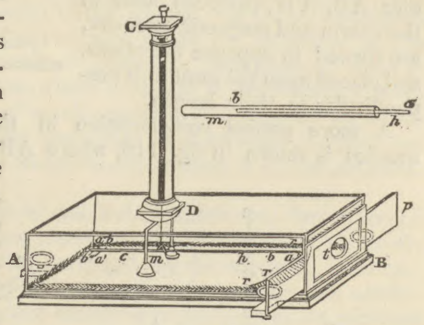

Fig. 113.

The object of this instrument, proposed by M. Lebaillif, is to detect minute degrees of magnetism by means of a very delicate combination of small magnetic needles. This apparatus, which he calls a *Sideroscope*, is shown in fig. 113, where ABCD represents the body of the instrument. The other parts consist of three sewing needles magnetized to saturation, and a tube of straw 12 or 15 inches long. One of these needles *ab*, is slid into the tube *mh*, and the others $a'b'$, $a''b''$, are placed across the straw, so that their dissimilar poles correspond. The straw thus fitted up is placed upon a small stirrup of paper, which is suspended by a silk fibre fixed at the top C of the vertical tube of glass or wood CD. The portion *mh* of the tube of straw is the longest, and it is beneath its extremity *a* that there is placed on the bottom of the cage or box AB, an arch *rrr*, divided into degrees and half degrees. The portion *mc* has no directive force, as the action of the earth is neutralized in the two opposed needles $a'b'$, $a''b''$. But the portion *mh* has a directive force depending on the magnetism of the needle *ab*, on its length, and on its distance from the point of suspension. The cage has a small sliding door *tp* which shuts up the apparatus; and when an experiment is made, the aperture at *t* is brought opposite the extremity *a* of the needle.

M. Lebaillif proved that almost all bodies exercise some action on the needle, and that *antimony* and *bismuth* always exert upon it a repulsive force. M. Pouillet, from whose work we have taken this description of the instrument, is of opinion that the movement of the needle may be often owing to atoms of iron; and that we must not take it for granted that in these phenomena the magnetic force is the only one which is acting.

SECT. XX.—*Description of the Astatic Needle.*

Astatic needle.

This instrument, described by M. Pouillet, is called the *Astatic Needle*, because it is withdrawn from the action of the earth's magnetism, and has no longer the statical position in which it is in equilibrio with the influence of this force. The construction of the astatic needle is founded on the principle that a body which is moveable round an axis cannot receive any motion from a force which acts parallel to this axis.

The astatic needle is represented in fig. 114, where *ns* is a magnetic needle, moveable round the axis *ab*. If this axis is placed in the direction in which terrestrial magnetism acts, the needle will rest in any position. This effect is easily produced by two motions perpendicular to each other, one of which is obtained by the milled head S, which, by an endless screw on its axis, works in the teeth of the wheel C, and the other by the milled head S′ and the wheel D; the graduated circle AB showing the positions of the needle.

Pouillet's astatic needles.

Another contrivance for an astatic needle is shown in the annexed figure (115), where two needles AB, A′B′, perfectly alike in their form and magnetic intensity, are turned in opposite directions, and placed upon the same axis perpendicular to their length.

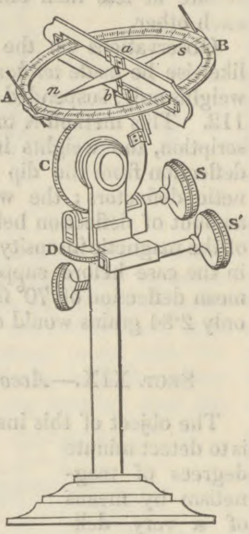

Fig. 114.

A more perfect compensation in the action of two needles is shown in fig. 116, where AB, AB are the two needles, the one horizontal and the other inclined to the horizon. It is obvious that the directive force of the latter will augment with its inclination, and it is therefore easy to make the directive forces of each perfectly equal and opposite, by varying the inclination of the uppermost one. These two contrivances we owe to M. Pouillet.

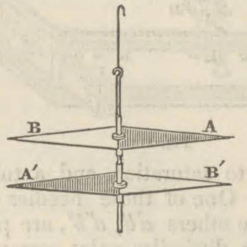

Fig. 115.

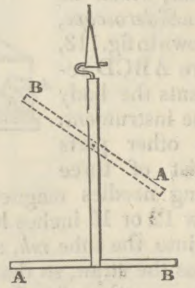

Fig. 116.

A magnetic needle may also be rendered astatic by neutralizing the action of the earth, by means of an equal and opposite magnetic action. For this purpose we have only to place a powerful bar-magnet at a considerable distance from the needle, so that it may act upon it as powerfully as the earth does. It should be placed in the magnetic meridian, parallel to the direction which the needle takes when it is in equilibrio, the pole of the bar which repels that of the needle being placed nearest it. When the bar is placed near the needle, it will cause it to wheel round, in consequence of its action exceeding that of the earth. At a very great distance, on the contrary, the earth's action will predominate, and draw the needle into the magnetic meridian; but an intermediate distance will be found in which the two actions exactly balance or compensate each other, and render the needle astatic.[1]

SECT. XXI.—*Account of Barlow's Correcting Plate or Magnetic Compensator for neutralizing the effect of local attraction on the Ship's Compass.*

Barlow's correcting plate.

As every ship contains large fixed masses of iron, beside moveable iron guns, anchors, cables, and iron utensils of various kinds, it is obvious, from the principles and experiments already detailed (see Chapter V., &c.), that these masses, rendered temporarily magnetic by the action of the earth, must produce derangements in the magnetic needles of the compasses on board. These derangements amount sometimes to 15° or 20°, and have exposed navigators to the most imminent perils. Mr Wales, the astronomer to Captain Cook's expedition of discovery, first discovered the fact that such a deviation existed, but he does not seem to have suspected its cause. Mr Downie, master of his Majesty's ship Glory, was the first person who pointed out the true origin of the deviation. "I am convinced," says he, "that the quantity and vicinity of iron in most ships have an effect in attracting the needle; for it is found by experience that the needle will not always point in the same direction, when placed in different parts of the ship. Also it is rarely found that two ships, steering in the same course by their respective compasses, will go exactly parallel to each other, yet these compasses, when compared on board the same ship, will agree exactly."[2]

In his survey of the coast of New Holland, in 1801 and 1802, Captain Flinders observed great differences in the direction of the needle, which arose only from changes in the direction of the ship's head, the direction being westerly when the ship's head was to the east, and *vice versa*. Hence he concludes, that the attractive powers of the different bodies in the ship which are capable of affecting the compass are collected into something like a focal point or centre of gravity, and that this point is nearly in the centre of the ship, where the shot are deposited, for here the greatest quantity of iron is collected together."[3] He likewise supposes that this magnetic centre is of the same name as the pole of the hemisphere where the ship is, and consequently, that in New South Wales the south end of the needle would be attracted by it, and the north end repelled; and from this hypothesis he concludes that the phenomena must be exactly the reverse in the northern hemisphere.

The Admiralty ordered a course of experiments to be made on this important subject; but though they established the truth of Captain Flinders' views, the subject was not farther prosecuted. The public attention, however, was again called to it by Mr Bain, who, in an excellent treatise on the variation of the compass, pointed out the fatal consequences which might result from this great source of uncertainty in the indications of the needle. The observations of Captains Ross, Parry, and Sabine threw additional light upon the subject; but it is to Professor Barlow alone that we owe a series of brilliant experiments, which terminated in his invention of the neutralizing plate, for correcting in a perfect manner this source of error in the compass.

In order to give an idea of the magnitude of this error, Professor Barlow published the following table of deviations actually observed:—

---

[1] See Pouillet's *Elemens de Physique.*

[2] Walker *on Magnetism*, 1794, cited by Prof. Barlow.

[3] *Phil. Trans.*, 1805, p. 186.

Ship.	Place.	Observers.	Deviation in the compass.
Conway	Portsmouth	Captain Hill	4° 32′
Leven	North fleet	Captain Owen	6 7
Barracouta	Do.	Captain Cuttfield	14 30
Hecla	Do.	Captain Parry	7 27
Fury	Do.	Captain Hoppner	6 22
Griper	Nore	Captain Clavering	13 36
Adventurer	Plymouth	Captain King	7 48
Gloucester	Channel	Captain Stuart	9 30

The instrument employed by Professor Barlow is shown in figs. 117 and 118, where T is a rod of copper an inch and a half in diameter, and F, F′ two plates of iron about 12 or 13 inches in diameter, and of such a thickness that a square foot of it will weigh about 3 lb. avoirdupois. These plates are separated by a circular sheet of card, and pressed against each other at their centre by a screw on the end of the rod T, and at their margins by three small screws of iron. The compass C is placed on the top of a wooden box, and the corrector T is placed in one of the holes in the side of the box.

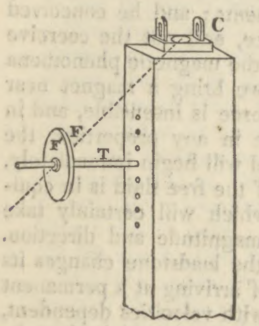

Fig. 117.

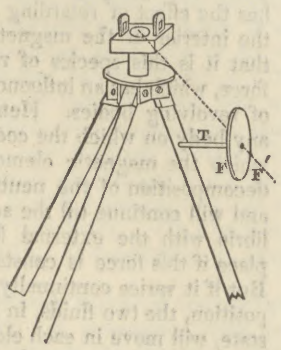

Fig. 118.

The adjustment of the plate is made when the ship is lying in a calm bay near the shore. An observer with a needle and theodolite is placed at some distance from the shore, from which he can perceive the ship while it is turning its head in different directions. The compass on board the ship is under the management of another observer with the same apparatus. At a signal given, the observer determines the angle which his own needle makes with the axis of the telescopes (one being directed to the other), which is called the central line. But as the needle on shore experiences no disturbing action, it is evident that if the needle on ship-board also experience none, the two needles will be parallel, and will form the same angle with the central line. Hence the difference between these two angles when they are not the same is that which is produced by the magnetic action of the iron in the vessel from its compass-needle at the instant of observation. Let the vessel be now made to turn round completely, and let a new observation be made at every azimuth of ten or twelve degrees, we shall then have the value of the deviation produced in all positions of the ship's head upon the compass-needle. When this is done, the observer on shore takes away his compass and replaces it with that of the ship, which he sets on the wooden cage shown in fig. 117, having different holes for receiving the axis T of the plates, F, F′. As the box is turned round its axis it carries along with it the compensator FF′, which will affect the needle of the compass C differently in different azimuths, and by a few trials it may be adjusted by means of the holes of its axis T to produce the very same deviation in the compass as was produced upon it when in the ship by the action of its iron. When it is done, the position of the centres of the plates F, F′, with regard to the needle is completely marked, and when it is taken on board the ship and placed in its proper position, the compensator is adjusted on the stand which carries the compass, as shown in fig. 118, so as to have exactly the same relative position as it had in the box.

Now since the compensator produces the same effect as the iron on ship-board does, the deviation will be *doubled* in place of being corrected; but this furnishes the means of making the correction. If the variation is found to be 36° W. by the compass *without the compensator*, and afterwards 40° with the compensator, the difference 40° − 36° = 4° shows that the compensator augments the variation 4°, and the iron on board the vessel as much. Hence the true variation will be 36° − 4 = 32°, or 40 − 4 − 4 = 32°. If the observations with the compensator had given a less result than without it, this would have shown that the action of the iron had diminished the declination, and the difference of the two observations must have been added to the first to have the true declination.

CHAP. XII.—THEORIES OF MAGNETISM.

Theories of magnetism.

The phenomena of magnetism, like those of every other branch of physics, have afforded the groundwork of many absurd and wild theories. The hypotheses of Descartes and Euler, which created in the interior of magnetic bodies canals and valves to admit or obstruct the subtle matter, to the agency of which they ascribed the attractive or directive power of magnets, are too ridiculous to deserve any notice in the present state of the science.

Theory of Æpinus.

M. Æpinus of St Petersburg was the first philosopher who discovered a rational hypothesis, which explained nearly all the phenomena of magnetism. This hypothesis of one fluid, however, of which we have already given a short account in our history of the science, was found insufficient for explaining the phenomena which are exhibited in the division and fracture of magnets; and although susceptible of a correction, which consisted in considering a magnet as composed of small particles of iron, each of which has individually the properties of a separate magnet, yet it did not afford a complete explanation of all the magnetic phenomena.

Theory of Wilcke, &c.

The hypothesis of two fluids, which was first proposed by Wilcke and Brugmann, was established by M. Coulomb, and was afterwards perfected by the masterly investigations of M. Poisson, who not only constructed mathematical formulæ which enable us to calculate all the minutest details of the phenomena, but has enabled us to comprehend physically how all the phenomena have been produced. The general equations at which he arrived have not yet, in every case, been resolved; but the particular conditions under which the integrations are possible have already, as we have stated, exhibited the most happy coincidence with experiment.

The hypothesis of two fluids supposes that they reside in each particle of iron; that they are neutral, and inert when combined as in soft iron; and that, when they are decomposed, the particles of the *austral* fluid attract those of the *boreal* fluid, and *vice versa*, while they each repel one another.

In order to account for the phenomena of the division and fracture of magnets, it is necessary to suppose, that when the united fluids are decomposed, the fluids undergo displacement only to an insensible distance. The minute portions of a magnetic body within which the motions and displacements resulting from decomposition take place, or in which magnetism exists, are called the *magnetic elements* of that body, and the small intermediate spaces where magnetism is not found, the *non-magnetic* elements. It is impossible to determine whether the *magnetic elements* are the intervals which separate the ultimate atoms of material bodies, or if they are the atoms themselves; nor can we ascertain whether they are the intervals between an aggregate number of atoms, or of a secondary molecule, or the aggregate members themselves. The theory regards the sum of the magnetic elements and of the non-magnetic elements as forming the apparent volume of a body. The ratio of these two sums may change with the nature and temperature of the body; and these changes exercise a powerful influence over the distribution and intensity of magnetism.

The quantity of each fluid in every magnetic element is unlimited in reference to our powers of separating them, as the united fluids can never be completely decomposed. The force which prevents this decomposition, and also the recombination of the fluids, is called the *coercive force*, and, like that of friction, it cannot be completely overcome. In soft iron this coercive force is extremely feeble. In the natural loadstone, and in steel, it is very powerful, varying in intensity in different kinds of this metal.

One of the most important consequences of the theory of Poisson is, that a magnetic needle whose size is so small that it exerts no sensible action on an iron sphere within which it is placed, will intercept the magnetic influence of the earth, and of all magnetic bodies without the sphere; and, in like manner, such a sphere will intercept the action of a magnet within it on all bodies without it. Another interesting consequence of the theory is, that in a hollow iron sphere, magnetized by the influence of the earth, or of any magnetic force the origin of which is at such a great distance that it may be considered as acting in parallel lines, although the magnetism is not confined to the surface of the sphere, and though its intensity may be determined for any particular point of the solid mass of the shell, yet it is determined only by the radius of the external surface, and the co-ordinates of the point upon which the forces act. When this point is very remote from the centre of the sphere compared with its diameter, each of the three forces is nearly in the direct ratio of the cube of the radius, and in the inverse ratio of the cube of the distance.

M. Poisson likewise applied his powerful mind to the explanation of the singular phenomena of magnetism produced by rotation. To the suppositions which his theory makes in order to explain the phenomena of magnetism induced by influence, he added another, namely, that all bodies exert upon the *boreal* and *austral* fluids a species of action analogous to the resistance of media, which action has the effect of retarding the motion of the two fluids in the interior of the magnetic elements; and he conceived that it is this species of resistance, and not the coercive force, which has an influence over the magnetic phenomena of revolving bodies. Hence, if we bring a magnet near any body on which the coercive force is insensible, and in which the magnetic elements are in any proportion, the decomposition of the neutral fluid will begin immediately, and will continue till the action of the free fluid is in equilibrio with the external force, which will certainly take place if this force is constant in magnitude and direction. But if it varies continually, or if the loadstone changes its position, the two fluids, in place of arriving at a permanent state, will move in each element with velocities dependent, other things being equal, on the resistance which the substance of the body opposes to them.

It is needless to enter into any further details respecting this very ingenious theory, as the later discoveries of Dr Faraday respecting electro-magnetic induction have enabled him to give a most satisfactory explanation of the diversified phenomena of magnetism in motion. (D. B.)

MAGNUS, ST, BAY OF, a large and beautiful bay on the W. coast of the mainland of Shetland, about 8 miles wide at its mouth, and afterwards expanding to about 11 miles, and extending 7 miles inland. It affords excellent anchorage for the largest vessels. The island of Papa-Stour is at the S. side of its mouth.

MAGONTIACUM, or MOGONTIACUM, shortened into Moguntia, a town of Gallia Belgica, now Mentz or Mayence, situated at the confluence of the Rhine and the Maine.

MAHABALIPURAM, a town of Hindustan, in Southern India, in the province of the Carnatic. It is noted for the celebrated ruins of ancient Hindu temples in the vicinity, dedicated to Vishnu, generally called the Seven Pagodas, though it is not known for what reason, as no such number exists here. There is a high rock, or rather a hill, of stone, about a 100 yards from the sea, covered with images, so thickly scattered as to convey the idea of a petrified town. On this hill a temple is cut out of the solid rock, with figures of idols carved in alto-relievo on the walls, and well finished. On an adjoining hill there is a gigantic statue of Vishnu asleep on a bed, with a huge snake wound round in many coils as a pillow; the whole cut out of one solid stone. A mile and a half to the southward of the hill are two pagodas, about 30 feet long by 20 wide. Near to these is the figure of an elephant as large as life, and of a lion much larger than life. There are here also other pagodas, and curious monuments of superstition. This town is said to have extended many miles to the eastward, into what is now covered by the sea; and there is every reason to believe that it was formerly a very large city. N. Lat. 12. 37., E. Long. 80. 15.

MAHABULESHWA, in Hindustan, a small town within the presidency of Bombay, situate on the summit of the range of mountains bearing the same name. In contrast with most other hill stations in India, this is totally free from malaria, and the place having, in many circumstances affecting health, a decided superiority over the more depressed and sultry tracts in its vicinity, was some time since selected as a sanatory station for troops; but after a short trial the project was abandoned, on the ground of the climate being unsuited to the acute diseases most common among the soldiers. It is, however, much frequented by invalid officers, for whose accommodation there is a sanatarium containing eight sets of quarters, and several detached bungalows. There are also about seventy private dwellings, many of them built of hewn stone. The number of visitors is steadily on the increase. The station was established in 1828 by Sir John Malcolm, the governor of Bombay. There is a small church, a subscription library, and a hotel; and the bazaar is well supplied. The elevation of the station above the sea is about 4500 feet. Lat. 17. 59., Long. 73. 41.

MAHANUDDY, a river of Hindustan, which has its source in Nowagudda, one of the petty native states, on the S.W. frontier of Bengal. It proceeds with a very winding direction towards the Bay of Bengal, receiving in its course the contributions of the Hutsoo and several other tributaries. Near the town of Cuttack it divaricates into the numerous branches inclosing or traversing the delta; the total length of its course being estimated at 520 miles. Its principal mouth is in Lat. 20. 20., Long. 86. 50.

MAHARAJPOOR, in Hindustan, a small town in the native state of Gwalior, or possessions of Scindia's family. This place was the key of the position of the Mahratta army on the 29th December 1843, when the battle took place between them and the British army under Sir Hugh Gough. The Mahrattas were driven from all points, lost 56 pieces of artillery, and retreated to the fort of Gwalior. The loss of the British was severe, amounting to 106 killed, 684 wounded, and 7 missing. No great disparity of numbers existed between the contending parties, the British having a force of 13,000, and the Mahrattas numbering about 15,000. A monument at Calcutta, constructed from the cannon captured on the field, commemorates the victory. Lat. 26. 29., Long. 78. 5.

MAHE, in Hindustan, a French settlement and seaport on the coast of Malabar, containing an area of 2 square miles. It is situate at a short distance from Tellicherry, on the banks of a river, which is navigable for large boats a considerable way up the country. Small vessels can also cross the bar, where there is a secure harbour. The town is neat, and contains many good houses. The principal export is pepper, which is produced in abundance in the surrounding country. It was taken possession of by the French in 1722, but was retaken by the British in 1761. It was restored at the peace of Paris in 1763, but was again taken in 1793. The British establishment, previously established at Tellicherry, was then removed to Mahe; but the place having been restored to the French at the general pacification of 1815, the British establishment was replaced in its original station at Tellicherry. The Carmelites have a church here. Pop. 2616. It is situate in E. Long. 75. 38. and N. Lat. 11. 42.

MAHIM, a town of Hindustan, is situate on the northern point of the island of Bombay. It possesses a small fort, originally intended for the defence of the channel running between it and Salsette. The town of Mahim stands at the point where the island of Bombay is connected with that of Salsette by a road running partly on arches of masonry, and partly on a causeway constructed by the government, aided by a munificent contribution from Sir Jamsetjee Jejeebhoy, a Parsee merchant of great wealth residing at Bombay. Here is the tomb of a Mohammedan saint, with a mosque attached to it; also a Portuguese church, with a college for Roman Catholic priests depending on it. It is 7 miles N. of Bombay fort. E. Long. 72. 54., N. Lat. 19. 1.

MAHMUD I., *Sultan of Turkey*, the son of Mustapha II., was born at Constantinople in 1696, and succeeded his uncle Ahmed III. on the Ottoman throne in 1730. He prosecuted the war which had been begun in the former reign against Nadir Shah of Persia. In 1734 the Russians commenced hostilities against the sultan, and in 1737 captured Oczakow and Kilburn. The Austrians joined them; but, after invading Wallachia, they were defeated at Krotska, and forced to accede to a disadvantageous peace in 1739. Not so honourable was the treaty struck soon afterwards between the Ottomans and Russians, by which the latter were allowed to retain part of the possessions they had captured. Meanwhile, a peace had been concluded with Persia in 1736, but was broken in 1743, and restored soon afterwards on terms unfavourable to the Ottomans. Mahmud died in December 1754.

MAHMUD II., *Sultan of Turkey*, the younger son of Abdul-Hamed, was born at Constantinople on the 2d September 1789, or, according to another account, on the 20th July 1785. He passed his early years in the Seraglio, engaged in the study of Turkish and Persian literature until 1808, when his brother Mustapha IV. was deposed and imprisoned, and himself raised to the throne, by Mustapha Baïraktar, pasha of Rusjuk. No sooner had he taken the sceptre than he appointed Baïraktar grand vizier, and boldly proclaimed his intention of prosecuting the reforms for which his uncle Selim III. had been deprived of his crown. He also restored the Nizam Jedid, or army organized according to European discipline. Startled at these proceedings, the Janissaries rushed to arms, besieged the grand vizier in his palace, and clamoured for the head of the sultan. At this crisis, Mahmud ordered Mustapha IV. and his infant son to be strangled, and his four pregnant sultanas to be sewn up in sacks and thrown into the Bosphorus. By thus becoming the sole male descendant of Osman, he rendered his person sacred in the eyes of his subjects, and was enabled more effectually to quiet the tumult. Then began his unsuccessful war with Russia, which was terminated by the peace of Bucharest on the 28th May 1812. Mahmud had for some time looked with a jealous eye upon the growing dominion of Ali, the ambitious pasha of Jenina, and he now strained all his energies to effect his overthrow. But no sooner had he succeeded in crushing him in 1822, than the Greeks broke out into open rebellion. Aided by the forces of Mehmed Ali, pasha of Egypt, the sultan suppressed this revolt with such sanguinary cruelty that Britain, France, and Russia interfered; and when their interference had been slighted, their combined armaments attacked and routed the Turko-Egyptian fleet in the Bay of Navarino in 1827. Meanwhile, at Constantinople, a desperate rebellion of the Janissaries, in 1826, had ended in the complete subjugation and dispersion of that order, and in the permanent establishment of an army organized according to the European system. Expecting that his soldiers, under their new discipline, would now be able to cope successfully with the armies of Europe, Mahmud declared war against Nicholas of Russia in 1828. After his forces had been cut to pieces, and General Diebitsch had occupied Adrianople, and Prussia, Britain, and France had interfered to effect a reconciliation, he unwillingly signed the treaty of Adrianople in 1829. With a determination untamed by so many reverses, the sultan now began to muster all his strength for the purpose of curbing the restless ambition of Mehmed Ali. The refusal of that pasha in 1832 to withdraw his troops from Syria, which his son Ibrahim had conquered in the preceding year, furnished Mahmud with a pretext for war. Accordingly, he commenced hostilities, but, with his usual ill fortune, was defeated by Ibrahim at Hems and Kouiah, and was only saved from total humiliation by the intervention of a Russian army. The result of this mediation was the treaty of Unkiar Skelesi, in which it was agreed that Russia should assist Turkey at any emergency with an armed force, and that Turkey in return should close the Dardanelles against all the foes of Russia. In 1834 another war between the sultan and Mehmed Ali was prevented by the interference of the European powers. In the midst of all these distractions from abroad, Mahmud had completed the reorganization of his army, had constructed roads, and had established postage communication throughout the country. Ambassadors were also stationed at Vienna, London, and Paris; and women, for the first time, were allowed to appear in public. Still intent, however, upon taking vengeance upon Mehmed Ali, he commenced hostilities in 1839, on the pretext of forcing that pasha to pay his arrears of tribute. His forces were defeated by Ibrahim near Nisibis; and he died on the 1st July 1839, before the news of the disaster reached Constantinople. He was succeeded by his eldest son, Abdul Mejid.

MAHOGANY, the timber of *Swietenia Mahogani* (Linnæus); Natural Order, *Cedrelaceæ*. The mahogany tree is a native of South America, Cuba, St Domingo, Jamaica, and especially of Honduras, and is one of the most magnificent and valuable of tropical timber trees. It grows rapidly, yet its timber is very hard and heavy; its height is from 80 to 100 feet, with usually a very straight stem of great diameter. It is commonly imported in logs from 2 to 3 feet square, of various lengths, not often exceeding 18 feet. That called Spanish mahogany is usually smaller, the logs being generally about 2 feet square by about 10 feet in length. The grain, or *curl*, as it is called, is sometimes so exceedingly beautiful that it raises the value of a log to an extraordinary price. More than L.1000 has been realized several times by the sale of a single log. Mahogany was introduced into England in 1595. By some the discovery of its value is attributed to the carpenter of Sir Walter Raleigh's ship; and another account states that it was first employed for cabinet-work in England in 1720, by one Wollaston, a cabinet-maker in London, who being accidentally requested to make some small articles from this wood for Dr Gibbons, a physician in that city, discovered its rare properties, which, on being made public, soon rendered both the workman and the material highly famous. It is chiefly imported from Honduras and Cuba. The average imports of the last five years are 38,000 tons, worth about L.500,000. (T. C. A.)

MAHOMET I., son of Bayazid I., was originally governor of the town and district of Amasia, and, after the death of his elder brothers, became Sultan of the Ottomans, A.D. 1413. He restored the Ottoman empire, extended his conquests into Bosnia, Servia, and Wallachia in Europe, and, after a reign of nine years, died A.D. 1421.

MAHOMET II., *Sultan of Turkey*, was born at Adrianople in 1430, and succeeded his father, Amurath II., in 1451. Bent upon overturning the Greek empire, he broke the truce that subsisted between the Turks and the Emperor Constantine, and in April 1453 beleaguered Constantinople with a large fleet and an army of 300,000 men. The Greeks, though only 10,000 strong, barricaded the mouth of their harbour with strong iron chains, and offered a determined resistance. The emperor himself was slain, fighting hand to hand with the besiegers. At last, however, by conveying a part of his fleet overland into the harbour, and by mounting a bridge of boats with cannon, Mahomet was able, after a siege of fifty-three days, to storm the city on the 29th May. Three days, devoted by his soldiers to massacre and pillage, rendered Constantinople desolate, and seemed to defeat Mahomet's design of making it his capital. Nevertheless, by granting to the Greeks religious toleration and the use of one-half of the churches that had survived the sack, he induced many of them to reinhabit the city. He also restored its fortifications, and erected at the mouth of the Hellespont the forts called the Dardanelles. In 1456 Mahomet, advancing westward, laid siege to Belgrade, but was defeated and forced to retreat by John Hunniades, general to Ladislaus, King of Hungary. More successful in his invasion of Greece, he subdued Corinth and the Morea. In 1461 he captured Trebisonde, and thus overthrew the dynasty of the Comneni. The islands of the Archipelago were added to his conquests in the following year. The Albanians, under their king Scanderbeg, had for some time successfully checked the advance of the Turks; but after the death of that prince in 1466, they too were subdued. From the republic of Venice Mahomet wrested Negropont in 1470. After taking the Crimea in 1475, he invaded Italy in 1480. No sooner, however, had he captured Otranto than he received the news that part of his forces had been foiled in their attempt to take Rhodes, by the knights who had fled thither after the sack of Constantinople. While he was preparing to retrieve that defeat he died in 1481. He was buried at Constantinople, and over his grave was written the following epitaph:—"I would have taken Rhodes and subdued Italy."

MAHOMET III. began his reign in 1595, as the successor of Mourad III., by putting to death all his brothers. He gave himself up to idleness and luxury, and before he could be roused from his sloth his troops were beaten in Hungary and elsewhere. He set out for that country with a large force, but after a few trifling successes, returned again to his capital, leaving his generals to prosecute the war. He died in 1603, while revolt raged in his Asiatic provinces, and mutiny in his capital.

MAHOMET IV., *Sultan of Turkey*, was born in 1642, and succeeded his father Ibrahim I. The chief exploits of his reign were those of the grand viziers Kuperli and his son Achmet. The Turks were defeated by the Hungarians at St Gothard, in 1664, by General Montecuccoli. The war with the Venetians, begun in 1645, was ended in 1669, when the town of Candia, after a siege of two years, capitulated to Achmet Kuperli. Encouraged by the internal discord of Poland under King Michael, the Turks successfully invaded that country in 1672; but in 1673 were routed by the famous John Sobieski, driven south of the Danube, and forced to sign a disadvantageous peace. In 1683 a horde of 200,000 men, under the grand vizier Kara Mustapha, marched westward, and encamped in front of Vienna. After a siege of six weeks, all hope of relief had been abandoned, when Sobieski, now King of Poland, attacked the Turkish forces, drove them from their entrenchments, and cut them to pieces. This was the first of a series of disasters that ended, in 1687, in an insurrection of the Janissaries, and in the deposition of Mahomet IV. He died in prison in 1691.

MAHOMETANISM. See MOHAMMEDANISM.

MAHRATTAS. The Mahratta state comprehended a country in Hindustan, very extensive, and of great natural strength, being interspersed with mountains, defiles, and fortresses, and well adapted for defensive war. It extended across the peninsula of India, and, generally speaking, was in possession of the peishwa, Nagpoor Rajah, Scindia, Holkar, Guicowar, and other inferior chiefs. The Mahrattas were not originally a military tribe, like the Rajpoots; nor do they possess the same grace and dignity of person, being of a diminutive stature and badly made, and having more the character of freebooters than of soldiers. Their original country is said to have included Khandesh Baglana and part of Berar, and to have extended N.W. as far as the Nerbuddah River. Others, again, say that they are foreigners who came into India from the western parts of Persia about 1200 years ago. Little is known of the history of the Mahratta people till about the middle of the seventeenth century, when they possessed a narrow tract of country on the western side of the peninsula, extending from N. Lat. 15. to 21. The founder of the Mahratta state, or at least the first person who raised this nation from obscurity, was Sevajee, who was born about the year 1626, and died in 1680, and who claimed a descent, but upon very doubtful grounds, from the ranahs of Odeypoor. The father of Sevajee, named Sahoo Bhosila, or Bhoonsla, was an officer in the service of the last Mohammedan king of Bejapoor or Visiapoor. The Mahratta country was originally divided amongst a number of principalities, ruled by independent chiefs, who at length acknowledged one leader, Sevajee. He was succeeded by his son Sambajee, who extended his conquests, but who was finally taken prisoner by Aurungzebe in 1689, and put to death. His son Saho, at the time of his father's death, was an infant and a captive. Saho was eventually liberated on the death of Aurungzebe, but found the succession contested by his cousin, as stated in the article COLAPOOR. His power was usurped by the two chief officers of the state, the peishwa or prime minister Balajee, and the paymaster-general Ragojee, who divided the empire between them. The former fixed his residence at Poonah; the latter founded a new kingdom at Nagpoor, in the province of Gundwaneh. Bajeerow, the second peishwa, died in 1759, and was succeeded by his son Ballajeerow. In 1760 the Mahrattas had extended their conquests as far as the city of Delhi, when a formidable rival appeared in Ahmed Shah Abdalli, the sovereign of Afghanistan, to dispute with them the empire of India. With the Afghans was fought, on the 7th of January 1761, the great battle of Paniput, in which the Mahrattas were speedily overthrown, with the loss of a great number of their chiefs. From this period their power began to decline. Ballajeerow died soon after the battle of Paniput, and was succeeded by his son Madhoorow, who died in 1772, and was succeeded by his son Narrainrow, who was murdered the following year by his uncle Ragobah, who was opposed in his designs on the throne by a combination of twelve chiefs. At the head of these was Ballajee Pundit, who became dewan or prime minister to the infant prince. Ragobah fled to Bombay, where he solicited and obtained, by means of an advantageous treaty, the aid of the British government. But this aid was ineffectual in seating the murderer upon the Mahratta throne. His crime had brought upon him the general obloquy of the nation; and his appeal to foreign aid united against him the whole confederate chiefs of the Mahratta empire. By the interference of the Bengal government, a treaty was concluded; but in 1777 the Bombay government again espoused the cause of Ragobah, and a war ensued which was terminated by a disgraceful convention, and Ragobah abandoned. A general war afterwards took place between the British and the Mahrattas, and was terminated by a treaty in 1782, by which every conquest was restored, except the island of Salsette. At this period the Mahrattas commenced hostile operations against all those independent states which lay between their territories and those of the Company; and in the course of six or seven years they were all subdued, by which the Mahratta frontier bordered with the British dominions. In 1785 they carried on an unsuccessful war with Tippoo, and were obliged to purchase peace by the cession of several valuable provinces, all of which they recovered by their alliance with the British in 1790. The posthumous and infant son of Madhoorow, who succeeded to the peishwaship when he came to maturity, died in 1795, and the two sons of Ragobah contended for the office. The cause of the eldest brother, named Bajeerow, was espoused by Scindia, by whose aid he was fixed on the throne; but he was permitted to enjoy nothing of the sovereignty but the name. In the year 1802 the united armies of the peishwa and Scindia were defeated by Holkar; and the former having taken refuge in the territory of the British, was, by their aid, reinstated on the throne, agreeing, in return, to a treaty offensive and defensive, and to receive into his pay a force of 6000 infantry, with the usual proportion of artillery attached, for the payment of which he assessed districts in the southern quarter of the country. From this period the peishwa, murmuring under his degradation into a state of dependence, cherished schemes of hostility against the British. The first overt act of hostility was the murder of the Guicowar's ambassador, through the agency of his ambassador Trimbuckjee. But his intrigues and schemes being discovered, he vowed the strictest fidelity in future; and in 1815 he delivered up his prime minister to the British. He soon contrived, however, to escape to the court of Poonah; and the peishwa, no longer dissembling, joined the confederacy which had at that time been formed amongst the native princes of India, namely, Scindia, Ameer Khan, Holkar, and the Berar Rajah, for the destruction of the British power. But this confederacy was signally overthrown; the peishwa's armies were entirely routed; and he, reduced to the character of a wandering fugitive, at last surrendered himself a prisoner to Sir John Malcolm, on condition of an allowance being assigned him. It was now resolved by the Anglo-Indian government to abolish the authority and the name of the peishwa, which had become a rallying point for the disaffected, and to occupy the whole of the Poonah dominions for the British nation, with the reservation of certain territories for the Satarah family. Thus was extinguished not only the political influence, but the name and authority, of the Mahratta state.

MAI, Angelo, a cardinal of the Roman Church, was born 7th March 1782, at Schilpario, a village of the province of Bergamo, in the Milanese territory. His parents were of the humblest peasant class; and he was placed, along with the other boys of the village, at the parish school, for the purpose of being initiated in the usual branches of elementary education. At this time, however, in consequence of the recent suppression of the Jesuit Society, and the dispersion of its members, a considerable number of ex-Jesuit priests were employed in the ordinary duties of the mission throughout Italy. One of these, Father Lewis Mozzi dei Capitani, a Milanese, who resided near Schilpario, was early struck by the remarkable abilities of Angelo Mai, and himself undertook to instruct him in Latin, Greek, and mathematics. About this time the Duke of Parma permitted the Jesuits to re-establish themselves at Colorno, in the duchy of Parma; and Mai, who was then about seventeen, accompanied his patron, Father Mozzi, to the college there opened, and with four youths of his native village, entered the novitiate of the society in 1799. He completed the novitiate in 1801, but remained at Colorno until 1804, when the society was more solemnly (though still only provisionally) re-established in the kingdom of Naples. To the college there founded Mai was sent as professor of Greek and Latin; but after somewhat more than a year and a half, he was transferred to Rome, when he completed his theological studies. Thence he was removed to Orvieto, where the bishop, M. Lambruschini, had invited the Jesuits to open a house. At Orvieto he was promoted to priest's orders; and remained partly engaged in teaching, partly in prosecuting his private studies, till 1808, when he was recalled to Rome. In that year, however, on the occupation of the Papal States by the French, an order was issued by the viceroy of Italy, requiring all natives of the kingdom of Italy to return to their respective provinces, and Mai was obliged to repair to Milan. As the Society was still unrecognised in the kingdom of Italy, Mai was compelled to seek for other occupation, and assumed the functions of a secular priest. After a time, through the influence of his first protector, Padre Mozzi, he was named an associate of the Ambrosian College, and soon afterwards a doctor of the Ambrosian Library. It is to his connection with this library that he is mainly indebted for his literary reputation.

Next to the unrivalled collection of the Vatican, the MS. treasures of the Ambrosian Library have long been celebrated in Italy for their number and importance. Enriched by contributions from the libraries of Bobbio, Lucca, Monte Cassino, and other great monasteries, the Ambrosian collection is now the depository of a large proportion of the literary treasures of the learned Benedictines of Italy; and although many of its MSS. had already been published or collated by the industrious editors of the seventeenth and eighteenth centuries, yet at the time when Mai was enrolled as an associate, it still contained enough to stimulate his curiosity and to exercise his learning. He had early acquired a taste for this branch of study under his first masters in the Jesuit Society, among whom were two learned Spanish fathers of some reputation in that department; and he now devoted a considerable time to a careful exploration of the Ambrosian MSS. His first publication was a Latin translation (accompanied by a critical commentary) of the recently discovered work of Isæus, *De Permutatione;* but he speedily relinquished the more beaten track of an ordinary editor or translator, and devoted himself to the then almost unknown department of palimpsest, or re-written MSS.—a class in which the Ambrosian Library is peculiarly rich. Up to this time but two or three palimpsest fragments had been deciphered and made public. In the course of a few years Mai was enabled to print two volumes of inedited fragments of Cicero's *Orations*, some orations of Lysimachus and Isæus, an interesting fragment of Plautus's lost comedy the *Vidularia*, and, above all, a large collection of the letters and other writings of Cornelius Fronto, the preceptor of Marcus Aurelius. The MS. from which these relics of Fronto were recovered had formerly belonged to the monastery of Bobbio, and was a translation of a part of the Acts of the Council of Chalcedon, written upon a series of palimpsest leaves, made up partly of an ancient MS. of Pliny the Younger, partly of an old commentator on Cicero, partly of some of the works of Lysimachus, and partly of letters of Fronto addressed to Antoninus Pius, Marcus Aurelius, Lucius Verus, and other friends,—all in a very disordered and mutilated condition, but yet sufficiently perfect to excite the curiosity of the learned throughout Europe. The most interesting circumstance, however, of the discovery is, that when Mai, some years later, was removed to the Vatican Library, he had the good fortune to find the remainder of this very palimpsest translation of the Acts of Chalcedon, *the counterpart of the Ambrosian palimpsest*, containing above a hundred additional letters of the same correspondence.

Meanwhile, the Jesuit Society had been formally revived by Pope Pius VII. on his restoration in 1814. But the services of Mai in his new position were so highly appreciated that, as he had never taken the solemn vows of the Order, he was induced to remain a member of the secular clergy. In 1819 he was invited to Rome to fill the office of chief keeper of the Vatican Library. Soon after his installation in this honourable and congenial office, he discovered that a MS. of St Augustine's *Enarrationes in Psalmo* was a palimpsest, the original of which had been no other than the long-sought work of Cicero *De Republica*. The commentary itself, unfortunately, was imperfect. It extended only from the 119th to the 140th psalm (the commentary on the ten remaining psalms being deficient); and even in the portion which remained there were gaps to the amount of sixty-four pages. Nevertheless, the skill and ingenuity of Mai recovered from these confused and obliterated fragments about one-fourth of the entire work, with which he interwove, in the edition which he published (Rome 1822), all the existing fragments of the original, collected from the numberless writers, sacred and profane, through whose writings they are scattered.

The design of the pope, however, in appointing Mai to the charge of the Vatican Library had been to engage him in a formal and systematic exploration of its contents, with a view to the publication of the most important remains of classical literature which still remain locked up in that great treasure-house. Mai, extending the plan, resolved to comprise in his collections the unpublished sacred as well as profane remains of the Vatican MSS., and, leaving to future scholars the task of critically editing, commentating, and translating, to secure for the world, in miscellaneous *Collectanea* similar to those of Muratori, Mabillon, Montfaucon, and their fellow-labourers, all that was really important among its inedited MSS. in every department of literature. On this plan he commenced, in 1825, a magnificent 4to publication,—*Scriptorum Veterum Nova Collectio é Vaticanis Codicibus Edita*,—which extended to 10 volumes, and comprises a vast number of unpublished remains of the Greek and Latin writers, sacred and profane. Several of the volumes are occupied with patristical remains. The second, which is almost entirely from a palimpsest source, contains an immense number of fragments of the lost books of the historians,—Polybius, Diodorus Siculus, Dionysius of Halicarnassus, Dion, Appian, and others, even so late as Dexippus and Eunapius.

In 1833 M. Mai was transferred from the office of Vatican librarian (in which he was succeeded by the celebrated linguist Mezzofanti) to that of secretary of the Propaganda; but he still continued his literary labours. He followed up the *Vaticana Collectio* by another collection in 8vo, equally miscellaneous, and indeed entirely similar in plan,—*Classici Auctores é Codicibus Vaticanis Editi*, 10 vols. 8vo (1828–38). In the year in which this work was brought to a close he was elevated to the cardinalate, and soon afterwards was named prefect of the Congregation of the Index, and of that of the Council of Trent, and eventually cardinal librarian of the Roman church.

The *Classici Auctores* was succeeded by a similar miscellany, but containing a larger amount of matter, *Spicilegium Romanum*, 10 vols. 8vo (1839–44). This collection, besides Greek and Latin writers, comprises also a few interesting Italian works, chiefly historical and biographical. His last publication was in 4to, *Nova Patrum Bibliotheca* (6 vols. 1845–53). It is almost exclusively patristical, and contains many highly important works, forming an indispensable supplement to almost all the existing patristical collections. Cardinal Mai had also undertaken to edit the celebrated Biblical *Codex Vaticanus*, and actually printed the text at the Propaganda press. He delayed its publication, however, with the intention of prefixing to the text an elaborate critical and historical introduction; but to the infinite disappointment of the learned, he died, leaving this great work incomplete, and indeed does not even appear to have made any progress in the preparation for it. Since his death, which occurred in his seventy-fourth year, at Albano, September 8, 1854, no trace of the expected biblical dissertations has been discovered. It is highly probable that the anxious and unsettled condition of political affairs at Rome during the years preceding his death, deprived him of the leisure or the spirit necessary for so laborious an undertaking. From the very nature of Cardinal Mai's collections it will be understood, that in very many of the works which he printed he contented himself with the mere rough work of publication. But in those which he undertook to edit critically, and especially in the *De Republica*, he appears as a master in the art. Even those works the text of which alone he printed, are accompanied by learned and judicious prefaces, which exhibit an amount of erudition such as few modern scholars can claim. His library was one of the most complete private collections in Rome. At his death he directed that it should be offered at half its estimated value to the Vatican Library, and that the proceeds of the sale should be applied to the use of the poor of his native village of Schilpario. (C. W. R.)

MAIANO, BENEDETTO DA, an eminent sculptor and architect, was born at Florence in 1424. He first became known as an inlayer of wood, and in this capacity he was employed at Naples by King Alphonso, and afterwards in Hungary by King Matthias Corvinus. Ambitious, however, to excel in a nobler art, he turned his attention to sculpture, and returning shortly after to Florence, he was employed by the magistrates of that city in the construction of their audience chamber. While sojourning for a short time in Naples, he executed a bas-relief in marble of the Annunciation. On his return to Florence, Maiano commenced one of his masterpieces, the marble pulpit of Santa Croce, ornamented with sculptured representations of the history of San Francesco. He was next employed in constructing the plan of the Palazzo Strozzo. Turning his attention about this time to architecture, he built, in addition to other structures, the portico of Madonna della Grazie, near Arezzo. After amassing a considerable fortune, Maiano died in 1498, and was buried in the church of San Lorenzo in Florence.

MAIDA, a small town of Naples, province of Calabria Ultra II., 8 miles S. of Nicastro, and chiefly famous on account of a victory gained here by the English over a superior French force on 4th July 1806. Pop. about 3000.

MAIDEN, an instrument anciently used for beheading criminals, resembling the guillotine of the French. It seems to have been first used in Britain within the limits of the forest of Hardwick. There is a machine of this kind in possession of the Society of Scottish Antiquaries at Edinburgh, introduced by the Regent Morton, who took a model of it as he passed through Halifax, and at length suffered by it himself. A machine precisely similar was used in Genoa in the beginning of the sixteenth century; and one is figured in the *Symbolicæ* of Bocchi, Bologna, 1574.

MAIDENHEAD, a municipal borough and market-town of England, county of Berks, on the S. bank of the Thames, 14 miles N.E. by E. of Reading, 22½ miles W. of London. It consists of one street about a mile long, well paved, and lighted with gas. The town has a guildhall, which is a fine building; a chapel of ease; places of worship belonging to the Baptists and Wesleyan Methodists; a national school; and several charitable institutions. The manufactures are unimportant; but the wealth of the surrounding country, and the position of the town on the high road between London and Oxford, render it a place of considerable trade, the principal articles of which are meal, malt, and timber. The market is held on Wednesday, and there are also three annual fairs. The neighbourhood is highly cultivated, and is studded with gentlemen's seats and villas. The high road here crosses the river by a fine stone bridge, and the Great Western Railway by a very elegant one of brick. The borough received its first charter from Edward III., and it is governed by a mayor, four aldermen, and twelve councillors. Pop. (1851) 3607.

MAIDSTONE, the county town of Kent, and a municipal and parliamentary borough, stands on a gentle slope on the right bank of the Medway, 34 miles E.S.E. from London. It was anciently called Caer Meguaid, or Medwig (the City of the Medway); and afterwards, by the Saxons, Medwegestan and Meddestane, whence it acquired its present name. It was formerly in the possession of the archbishops of Canterbury; and their Gothic palace, dating from 1348, is still standing, though considerably altered from its ancient form. In the civil war Maidstone was taken by the parliamentary forces under Fairfax in 1648. A college was founded here by Archbishop Courtenay in the time of Richard II., but was suppressed about the time of the Reformation. Maidstone has always returned two members to Parliament since the time of Edward VI., from whom, and from various succeeding monarchs down to George II., it received charters. The town consists of four main streets, meeting in the market-place, together with several smaller ones. The sloping character of the ground on which it is built keeps the town clean and dry, and it is well supplied with water from the Medway. Of the public buildings, the chief is the parish church, built in the fourteenth century, and reckoned one of the largest edifices of the kind in England. It has recently been restored in a very splendid style. There are, besides, various other places of worship for different denominations. It has also a county hall, an extensive gaol, erected lately at the cost of L.200,000, and covering 13 acres, a town-hall, a corn exchange, a theatre, ball-rooms, and other buildings. There is a school called All Saints College, founded in 1846, occupying a portion of the buildings of the college which formerly existed here; also a free grammar school, a Blue-coat and a Brown-coat school for clothing and educating poor children, national schools, &c. The only manufacture for which Maidstone is remarkable is that of paper, of which there are a number of mills in the neighbourhood. The surrounding country is extremely beautiful, by reason of its orchards and hop gardens; and the circumstance which has contributed most to the prosperity of the town is the fertility of the neighbourhood. The river is here crossed by an old bridge of seven arches, and is navigable for vessels of sixty tons up to the town. Maidstone is connected with London by a branch of the South-Eastern Railway, by which route the distance is 56 miles. Market-days, Thursday and Saturday. The borough is governed by a mayor, six aldermen, and eighteen councillors. Pop. (1851) 20,801.

MAILLA, Joseph-Anne-Marie de Moyriac de, a learned Jesuit, was born in Bugey, on the borders of Savoy, and appointed a missionary to China, whither he proceeded in 1703. At the age of twenty-eight he had acquired such skill in the characters, arts, sciences, mythology, and ancient books of the Chinese, as to astonish even the learned men of the celestial empire. Besides constructing maps of China, Chinese Tartary, and the Chinese provinces, Mailla also translated the *Great Annals of China* into French, and his MS. was transmitted to France in the year 1737. This work was published in 1737 in 13 volumes quarto, and is the first complete history of that extensive empire. Mailla died at Pekin on the 28th of June 1748, in the seventy-ninth year of his age.

MAI-MAITCHIN. See Kiachti.

MAIMBOURG, Louis, a celebrated Jesuit, descended from a noble family, was born at Nancy in 1610. At the age of sixteen he entered the Society of Jesus, and was sent to Rome to study theology. On his return to France, he became a classical teacher in the college of Rouen; but afterwards devoted himself to preaching, and occupied in turn the principal pulpits in the kingdom. Not until Maimbourg had reached the middle stage of life did he produce any of those historical works upon which his fame rests. In 1682 he appeared as a bold defender of the liberties of the Gallican church in his *Traité Historique de l'Eglise de Rome*, a treatise which caused the immediate expulsion of its author from the Order of the Jesuits by the command of Pope Innocent XI. As a compensation, however, for this misfortune, Maimbourg was presented by Louis XIV. with a pension, and with the abbey of St Victor at Paris as a place of retirement. He died there of apoplexy on the 13th August 1686, leaving unfinished his *Histoire du Schisme d'Angleterre.* A collection of Maimbourg's histories, published in 14 vols., Paris, 1686–87, includes, besides the work mentioned above,—*Histoire de l'Arianisme, Histoire des Iconoclastes, Histoire du Schisme des Grecs, Histoire des Croisades, Histoire de la Décadence de l'Empire, Histoire du Grand Schisme d'Occident, Histoire du Luthéranisme, Histoire du Calvinisme, Histoire de la Ligue, Histoire du Pontificat de Saint Grégoire le Grand*, and *Histoire du Pontificat de Saint Léon.* Although once in great repute, Maimbourg, as a historian, has no longer any authority; yet Voltaire, a critic by no means guilty of partiality to churchmen, says that Maimbourg "was formerly in too great vogue, and has been latterly in too great neglect."

MAIMONIDES, or Ben Maimon Moses, a celebrated Jewish rabbi, was born at Cordova in Spain, probably about 1131. After receiving the elements of his education from his father, he studied philosophy and medicine under the learned Arabians Thophail and Averroes. He also perused with avidity the ancient philosophers, especially Aristotle, and thus incurred the dislike and suspicion of his Jewish brethren. Soon after this he repaired to Egypt; and from remaining there during the rest of his life, he acquired the title of *Moses Ægyptius.* There he at first followed the vocation of a jeweller; but resorting afterwards to the practice of medicine, he became so eminent in this profession, that he was appointed chief physician to the Sultan Saladin. While holding this office, Maimonides is said to have also taught with great success in a school which he had founded. He died in Egypt at an advanced age. In addition to a thorough knowledge of philosophy and medicine, Maimonides possessed an acquaintance with mathematics, theology, and the jurisprudence of the Jews. He knew several languages, and wrote Arabic and Hebrew with facility. By his Jewish admirers he was surnamed "The Eagle of the Doctors," and "The Lamp of Israel." Of his numerous works three are chiefly notable. His "*Moreh Nevochim* (Teacher of the Perplexed"), written originally in Arabic, but afterwards translated into Hebrew, is an exposition of the obscure words, allusions, types, and allegories in Scripture. A translation into Latin by the younger Buxtorf, 4to, Basel, 1629, has been retranslated into English by Dr Townshend, London, 1827. The original Arabic, accompanied with a French translation, has been published under the title, *Le Guide des Egarés, traité de Théologie publié en Arabe avec Traduction et Notes par S. Munk*, 8vo, Paris, 1856. The Arabic text of the *Moreh Nevochim* exists in the Bodleian Library, Oxford. In *Yad Hazakah* ("The Strong Hand"), written in good Hebrew, Maimonides gives a digest of the Talmud, stripped of all its rabbinical fables. The best edition of this work is that in 4 vols. folio, Amsterdam, 1702. His *Perush Ha-Mishna* ("Commentary on the Mishna"), originally written in Arabic, has been often translated into Hebrew by different rabbis, and printed along with the *Mishna*. Part of this work, in the original Arabic, was published by Pococke, Oxford, 1655. MSS. of the works of Maimonides are found in the great libraries of Paris, Berlin, &c.

MAIN, MAINE, or MAYN (the ancient *Mœnus*), formed by the union in North Bavaria, about 14 miles N.W. of Bayreuth, of two streams, the Red and White Main, which have their sources in the Fichtelgebirge. It has a very irregular and winding course in a direction generally westerly, and falls into the Rhine nearly opposite to Mentz. It is about 280 miles in length, and is navigable as far as its junction with the Regnitz, near Bamberg, about 240 miles from its mouth. As early as 793 Charlemagne had projected the formation of a canal between the Altmühl and the Pegnitz, an affluent of the Regnitz, and so connecting the Main and the Danube; but it is only very recently that this has been effected. The chief tributaries of the Mayn are,—the Regnitz, Tauber, Mümling, and Gersprenz from the S., and the Rodach, Saale, Kinzig and Nidda from the N. The principal towns on or near its banks are Bayreuth, Bamberg, Würzburg, Aschaffenburg, Hanau, Offenbach, and Frankfort.

MAINE, one of the United States of North America, lying between N. Lat. 43. 5. and 47. 30., W. Long. 66. 50. and 71., and bounded on the N. by the St John River, which separates it from Canada; on the E. by New Brunswick; on the S.E. and S. by the Atlantic; and on the W. by the state of New Hampshire and Canada. Length about 200 miles; average breadth 160; area 31,766 square miles. It is the largest of the states of New England, of which it comprises nearly one-half. The face of the country is covered with an undulating surface of hill and dale; and although it has no marked mountain ridge, a succession of isolated hills, which form the termination of the White Mountains in the neighbouring state, extends across the country towards the N.E., and forms the watershed between the basin of the St John on the N., and the rivers that flow to the Atlantic on the S. Of the mountain summits, the highest is Katahdin Mountain, which attains the elevation of 5385 feet above the sea. The sea-coast is bold and precipitous, frequently indented with bays and inlets, many of which form very good harbours. The coast is also skirted with islands, for the most part of small size, and said to amount to the number of 365. The fishing in these parts is very good. The most marked natural feature of the state, however, is its rivers and lakes, which are calculated to cover one-tenth of the entire area. The largest rivers are the Penobscot and the Kennebec, which flow from the elevations in the centre in a S.W. direction, and discharge their waters into the Atlantic. The former, which is the more easterly of the two, is the largest river in the state, and has a length of 350 miles. The rivers of Maine are remarkable for their abrupt windings and falls, which, however, do not prevent the conveyance of timber rafts from the thick forests with which the interior is covered, and which supply one of the principal articles of export. The rivers are also useful as affording water-power to the many mills on their banks. The Penobscot is navigable for the largest vessels as far as Bangor, 60 miles from the sea; but for several months in the winter it is blocked up with ice. The lakes are very numerous, and remarkable for their irregular shapes, and for the wild beauty of their scenery. The largest is Moosehead Lake, about 50 miles in length, and varying from 5 to 15 in breadth. When the country becomes better inhabited, these sheets of water are likely to prove most useful as means of communication.

Geologically, the state of Maine is chiefly composed of primary rocks, though towards the E. there is to be found a tract of land of the secondary formation. The rocky barrier which extends along the sea-coast is composed of igneous formations, and granite is found in great abundance throughout the state. Marble and limestone are also extensively quarried in the country; indeed, it is from Maine principally that the whole of the states are supplied with lime. Trap dykes occur frequently; and on many accounts this district is interesting to the geologist. Iron is found of an excellent quality, and in considerable abundance; some traces of coal have also been observed; and on some of the eastern tributaries of the Penobscot gold has been found, but not to any great amount. The soil is generally rich and fertile, though towards the coast and among the mountains it is sandy and barren. The best soil is found in the country lying between the Penobscot and the Kennebec; and the chief articles of agriculture are potatoes, oats, and Indian corn. Of the natural products, the most remarkable are the forests of white pine, which are so extensive as to give to one district the name of "White Pine Land." Oak, ash, and beech trees, also grow in great quantities; and this, along with other circumstances, has contributed to render Maine the state most remarkable for ship-building in the Union. During the year ending 30th June 1855, 639 vessels of various kinds, including 6 steamers, and having an aggregate burden of 215,904 tons, were built in this state; while the total number of vessels built in all the other states of the Union during that period was only 1385, with an aggregate burden of 367,546 tons, or less than double the amount of tonnage built in this state alone. The climate in winter is very severe, the frost lasting from December to April, and so intense, that the largest rivers may be crossed on the ice; while in summer the heat is very great. The thermometer ranges between 100° in summer, and 28° below zero in winter; but the country is remarkably healthy; and towards the coast the severity of the cold is moderated by its proximity to the gulf stream. The inhabitants are principally the descendants of the ancient British colonists, though there are still about 500 of the original Indians, dwelling chiefly on the islands of the Penobscot, which belong to them, and drawing a considerable annuity from the government. There are also many emigrants from other countries, but by no means in such large proportions as in most of the other states. This state is not so extensively engaged in manufactures as some others in New England. The principal branches followed here are the iron, woollen, and cotton manufactures, besides ship-building and the tanning of leather. The products of the iron forges, &c., were, in 1850, 5175 tons, valued at L.62,837; of the cotton factories, 32,852,556 yards, valued at L.540,908; of the woollen manufactures, 1,023,020 yards, valued at L.157,139; and of the tanneries, leather to the value of L.340,633. Its commerce, however, is considerable, owing to the number and excellence of its harbours. The principal articles of export are timber and fish. The total value of exports during the year ending June 30, 1855, was L.937,868, comprising

L.529,794 of domestic, and L.408,074 of foreign produce. Of the imports at the same date, the total value was L.610,084, of which L.287,336 were conveyed in American, and L.331,748 in foreign vessels.

This state is divided into 13 counties. The capital is Augusta, on the Kennebec, though the largest and most commercial town is Portland, on Casco Bay. The extent of railways in the state in January 1856 was about 480 miles, the principal lines being the Androscoggin and Kennebec, the Atlantic and St Lawrence, the Kennebec and Portland, and the Penobscot and Kennebec; and there is also a canal of 50 miles in length, uniting Portland with Sebugo, Brandy, and Long Ponds. The government of Maine is in the hands of a governor, who is elected annually by popular vote, and he is aided by a council of 7, chosen by the legislature by ballot. The legislature consists of a Senate of 31, and of a House of Representatives of 151 members, both also elected annually. The right of suffrage is possessed by all males above twenty-one years of age, who have been resident in the district for three months immediately before the election. The constitution of the judiciary courts has been altered in 1852. The state is divided into three districts, and the courts are held annually at Portland for the western, at Augusta for the middle, and at Bangor for the eastern district. Among the public institutions are,—the state prison at Thomastown, which is managed on the silent system, and where the prisoners are employed in stone-cutting and quarrying; the state reform school, opened in 1853 at Cape Elizabeth for juvenile delinquents, where they are employed in various labours; and the lunatic asylum at Augusta, opened in 1840. For the purposes of education the state has a separate fund, collected from the various sources, of which there was expended for the year ending April 1, 1855, L.102,304. According to the census of 1850, there were 4042 public schools in the state, besides 131 academies and other schools, 2 colleges, 1 theological seminary, and 1 medical school. The whole value of property in Maine in 1850 was L.20,159,556; and the public debt amounted in 1856 to L.145,000. The number of churches in the state in 1850 was 851, of which there belonged to the Baptists 283, to the Christians 9, to the Congregationalists 12, to the Episcopalians 8, to the Free Church 19, to the Friends 4, to the Methodists 171, to the Presbyterians 7, to the Roman Catholics 11, to the Union Church 83, to the Unitarians 15, and to the Universalists 53; giving, on an average, one church to every 685 persons. The total amount of church sittings was 321,167. The first settlement effected in Maine was at Phippsburg in 1607; but this was soon afterwards abandoned, and the country was colonized from the neighbouring districts. In the latter part of the seventeenth century this state was the occasion and the scene of many conflicts between the British and the French, till it was finally secured to the former by the peace of Utrecht in 1712, at which time it was attached to Massachusetts. The town of Portland was bombarded by the British in 1775, when much property was destroyed. In 1820 this state was separated from Massachusetts, and received as a distinct state into the Union; and in 1842, after much negotiation, the boundaries between it and Canada were finally settled between Great Britain and the United States. Pop. (1850) white, 581,763; coloured, 1325; total, 583,088.

Maine, an old province in the W. of France, bounded on the N. by Normandy and Perche, on the E. by Orleanais, on the S. by Touraine and Anjou, and on the W. by Bretagne. It was divided into Upper and Lower Maine, and formed, along with Perche, the military government of Maine. It now forms, with the addition of some parts of Higher Anjou, the department of Sarthe and Mayenne.

MAINE DE BIRAN, Francois-Pierre-Gonthier, a distinguished philosopher of France, the son of a physician, was born at Bergerac on the 29th November 1766. After studying with distinction under the *doctrinaires* of Perigueux, he entered the Life-Guards of Louis XVI., and was present at Versailles on the notable 5th and 6th of October 1789. On the breaking up of the *garde du corps*, Maine de Biran retired to his patrimonial inheritance of Grateloup, near Bergerac, where his sequestered residence and limited income preserved him from the horrors of the Revolution. It was at this period that, as he says himself, he "passed *per saltum* from frivolity to philosophy." The forced leisure of this fearful time decided the vocation of his life. He combined, in a more than ordinary degree, subtle sensitiveness to external influences with singular acuteness in surveying and analyzing internal phenomena. The modes of the mind and their organic causes or conditions were alike submitted to his scrutiny. He began his philosophical studies with psychology, and he made psychology the study of his life. When the Reign of Terror was succeeded by calmer days, Maine de Biran was called to take part in the administrative and political affairs of his country. After his exclusion from the Council of the Five Hundred, on being suspected of royalism, he took part with his friend Lainé in the commission of 1813, which gave expression for the first time to direct opposition to the will of the emperor. Under the Restoration, Maine de Biran held the office of treasurer to the Chamber of Deputies, and habitually retired during the autumn recess to his native district to pursue his favourite study. He died 16th July 1824.

Maine de Biran ranks among the earliest of the rational psychologists of France, who, in the beginning of the present century, raised a protest against the exclusive sensationalism of the school of Condillac. Maine de Biran was originally a disciple of Cabanis and De Tracy, but afterwards abandoned their system to adopt an absolute spiritualism closely resembling that of Leibnitz. He rejected, however, the pre-established harmony of the German philosopher, and endeavoured to explain the phenomena which that celebrated theory was meant to rationalize, by resolving mind and matter into forces identical in their nature, but differing in the modes of their activity. All objects, external and internal, are recognised by consciousness only as forces, more or less active, more or less passive. To explain the phenomena of external perception on those principles, is accordingly an easy matter with Maine de Biran. You can dispense with the mediate object of the representationalists; you have no need of the hypothesis of occasional causes or of pre-established harmony; you are saved the humiliation of taking refuge in your ignorance, and bowing down before a mystery; your dead matter and living mind are not two distinct substances,—the relations of body and soul are only relations of forces of action and reaction. The theory of causation of Maine de Biran is the portion of his philosophy which is most generally known in this country; and Sir W. Hamilton, in commenting on it, terms its author "one of the acutest metaphysicians of France." The casual judgment is regarded by Maine de Biran as an original *à posteriori* cognition, given through a self-consciousness of the efficiency of our own volitions. M. Cousin, who is constant in his laudation of the originality of his countryman, characterizes him as "the greatest metaphysician of France since Malebranche." A complete edition of the *Œuvres Philosophiques de Maine de Biran* was published by M. V. Cousin, 4 vols. 8vo, Paris, 1841.

MAINE-ET-LOIRE, a department in the W. of France, including the most part of the province of Anjou and the W. part of Touraine, and lying between N. Lat. 46. 59. and 47. 45., and between 0. 15. E. and 1. 18. W. Long. Its greatest length is 77 miles, its greatest breadth 60, and its area 2756 square miles. It is bounded on the N. by the departments of Mayenne and Sarthe, on the E. by that of Indre-et-Loire, on the S. by those of the Vienne, the Deux Sevres, and La Vendée, and on the W. by that of the Loire-Inferieure. This department receives its name from the two rivers Maine and Loire, which unite here. There are no mountains of any importance in the department, but the ground consists of an undulating plain, diversified here and there by vine-covered hills. A small portion, however, at the N.W. extremity is occupied by the hills which separate the valleys of the Vilaine and the Loire, and the southern part is covered by a continuation of the hills of Gâtine. The most important river in the department is the Loire, which passes through it from E. to W., dividing it into two nearly equal parts. Besides this, it is watered by the Authion, the Maine, the Sarthe, the Mayenne with its tributary the Oudon, the Erdre, and the Thouet in the N.; while in the S. there may be noticed the Layon, the Erve, the Sevre-Nantaise, and the Moine, several of which are navigable rivers, while they all contribute to the fertility of the neighbouring country. The department is very productive, and the principal occupation of the inhabitants is agriculture. The corn produced is considerably more than sufficient to supply the wants of the inhabitants. The principal of the other productions are,—potatoes, hemp, flax, nuts, and fruits of various kinds. About 11,000,000 gallons of wine are made annually, besides a considerable amount of cider. The forests of this department are extensive, and consist principally of oak and beech. The pasturage is very good, and large quantities of live stock are annually reared, especially along the banks of the principal rivers. It has been calculated that there are in this department 210,000 head of large cattle, 200,000 sheep, 86,000 pigs, 4300 goats, 40,000 horses, and 3600 mules and asses. The forests abound in deer and wild boars, and there are also found numbers of foxes and weasels. The game and fish are very plentiful. Coal mining is carried on to a considerable extent, but the quantity produced, amounting to about 200,000 cwt. annually, is entirely consumed in the department. There are also considerable slate mines, situated chiefly round the town of Angers, where they give employment to 3000 workmen, and produce annually about 80,000,000 slates. Iron is also found, though in no great abundance; but it furnishes materials for several furnaces. There are also quarries of granite, marble, sandstone, limestone, &c. There is not much manufacturing industry in this department, but what there is has its chief seat about Cholet; and its principal products are linen, cotton, and woollen stuffs; Maine-et-Loire being especially famous for its handkerchiefs. There are also several breweries and distilleries, as well as tanneries and manufactories of bricks, tiles, pottery, and other articles. The trade of the district consists chiefly in cattle, grain, wines, linen, and dried fruit.

This country was anciently occupied by the Andes, or Andecavi, from whom the name Anjou is derived; and many Gallic monuments are still to be seen in the department. It was afterwards in the hands of the Romans, who have also left traces of their occupation. During the time of the Revolution this neighbourhood is remarkable as having been the seat of the war of La Vendée. This department is divided into five arrondissements as follows:—

	Cantons.	Communes.	Population.
Angers	9	89	154,945
Baugé	6	66	79,713
Segré	5	61	62,080
Beaupréau	7	76	121,375
Saumur	7	83	97,339
Total	34	375	515,452

MAINTENON, Madame de, descended from the ancient family of D'Aubigné, was born in 1635 in the prison of Niort in Poitou, where her profligate father was then confined. Her parents by misfortunes being unable to support her, she was intrusted to the care of her mother's relations; and, to escape this state of dependence, she was induced, in 1651, to marry the Abbé Scarron, a celebrated burlesque writer, who was deformed, infirm, and, as she insinuates in one of her letters, impotent, with no other means of support than a small pension allowed him by the court. When Scarron died in 1660, she found herself as indigent as she had been before her marriage. But Louis XIV. afterwards made choice of her to take charge of the education of the young Duke of Maine, his son by Madame de Montespan, and he was so charmed with the letters she wrote on this occasion, that he bought her the lands of Maintenon; and finding that she was pleased with the acquisition, called her publicly *Madame de Maintenon.* About the close of the year 1685, Louis XIV., being then in his forty-eighth, whilst she was in her fiftieth year, raised her from the condition of a mistress to that of a wife. By consummate art and address, concealed under a mask of affected simplicity and piety, she attained the grand object of her ambition; and though not publicly acknowledged, became in reality the second person in the state, and took part in some of the most disgraceful acts of that reign. She prevailed on Louis to found a religious community at St Cyr, for the education of 300 young ladies of quality; and on the death of Louis in 1715, she retired thither, where she spent the rest of her days in acts of devotion. It appears that her husband left no fixed provision for her, contenting himself with recommending her to the Duke of Orleans. She accepted a pension of 80,000 livres, which was punctually paid her till her death, which took place in 1719. A collection of her letters has been published, and translated into English.

MAIRWARRA, or *Realm of the Mairs*, in Hindustan, a mountainous tract, consisting of a number of parallel ridges extending in a direction from N.E. to S.W., and constituting that portion of the Aravulli range which lies between Komulmer and Ajmere, a space of about 90 miles in length, and varying in breadth from 6 to 20. The tract is interposed between the Rajpoot states of Oodeypore and Joudpore. Its north-eastern extremity is in Lat. 26. 10., Long. 74. 30.; its south-western in Lat. 25. 25., Long. 73. 50. Mairwarra was ceded to the British in 1818 by Scindia, but the states of Oodeypore and Joudpore having urged claims to a portion of the country, their validity was hastily and unadvisedly recognised. The inconvenience of three independent states claiming to exercise the powers of government in a country so circumstanced was, however, subsequently mitigated by arrangements under which the whole was placed under British management. The principal place in the district is the newly-established town of Nya Nugga, which promises to be the seat of considerable trade. British Mairwarra contains an area of 282 square miles, with a population of 37,715. The portion allotted to Oodeypore has an area of 305 square miles, and that belonging to Joudpore a superficial extent of about 67 square miles.

MAISTRE, Louis Isaac le. (See Sacy.)

Maistre, *Count Joseph Maire de*, a statesman and philosopher, was born at Chambery in Piedmont, on the 1st April 1753. His father, who held the honourable office of president of the senate of Savoy, directed his education with much care; and the industry and success of the son amply rewarded the solicitude of the parent. Having completed his education at the university of Turin with great distinction at the age of twenty, the following year saw him elevated to the rank of a magistrate, and in 1788 he was promoted to the dignity of a senator. On the French invasion in 1792 he was compelled to take refuge in Lausanne, where he remained till 1797, when he returned to Piedmont, only to leave it again for Venice. He remained in the latter city till 1800, when a call from the King of Sardinia to occupy an important political position in connection with the government of that kingdom, induced him to embark again in public life. Count de Maistre was sent as an ambassador to St Petersburg in 1803, where he remained till 1817. He died on the 26th February 1821, in his sixty-eighth year.

The writings of Count de Maistre are of a twofold character. The *Soirées de Saint Petersbourg*, and the *Examen de la Philosophie de Bacon*, belong more properly to philosophy; while the *Essai sur le Principe Générateur des Constitutions Politiques; Le Pape;* the *Considerations sur la France*, &c., are devoted to an exposition and defence of the political and social views of the author. The *Soirées*—which, by its popular form, its nervous and picturesque style, and the vigorous talent and pleasant wit which pervade it, exerted great influence—runs through a series of subtle metaphysical questions, handled with the apparent ease of a man of the world, and with all the grace of unstudied conversation. But his philosophy is more the reflex of his social ideas and political feelings than the product of calm reflection and steady adherence to the phenomena of observation. The principal design of De Maistre's philosophy is to justify or explain the temporal government of Providence; to show that the sufferings to which mankind are subjected are in no wise contradictory of the attributes of the Deity. He maintains that the good and the bad are alike subject to calamities, but that the good have less to suffer than the bad; that the good man suffers not as good, but as man; that man suffers in consequence of original sin; and that our only deliverance consists in personal prayer and the intercession and merits of the good employed in our behalf. He sums up his scheme of moral government by alleging, that "sovereignty and punishment are the two poles upon which God has poised the world." As for his religious and political sentiments, he advocates the divine right of legitimate sovereigns, passive obedience, the authority of the church in matters of faith, the supremacy of the pope, and the superiority of ecclesiastical over temporary authority. His system betrays two peculiar tendencies,—the one towards asceticism, the other towards mysticism. A complete edition of De Maistre's works was published at Paris 1821–36.

MAITLAND, Sir Richard, a cultivator and preserver of Scottish poetry, was the son of William Maitland of Lethington, and of a daughter of George Lord Seaton. He was born in 1496, and after passing through a regular course of study at the university of St Andrews, he repaired to France, in accordance with the custom of that age, to finish his education. There he devoted himself chiefly to the study of law. On his return to Scotland, Maitland successively held office under James V., the Regent Arran, and Mary of Guise. In the government of the last, according to Sir John Scot, he was lord privy seal. He was appointed an extraordinary lord of session in 1551, and was knighted soon afterwards. In 1561 he celebrated the landing of Queen Mary by his ode on *The Quenis Arryvale in Scotland*, and from this poem we learn that its author had already lost his sight. Yet this deprivation, interfering to no great extent with his professional activity, did not retard his promotion. In this same year he was nominated an ordinary lord of session; and in 1562 a member of the privy council and lord privy seal. This last office he resigned in 1567 in favour of his second son, afterwards Lord Thirlstane. The blindness, as well as the peaceful disposition of Sir Richard Maitland, prevented him from mingling in the civil broils that followed the death of Darnley and the marriage of the queen with Bothwell. Yet, on account of the conduct of his eldest son, the famous secretary of Mary, his estate was seized by the king's party, and not till after the fall of the Regent Morton was it restored. In 1583 he received from the lords of session an exemption from regular attendance on his judicial duties, and he retired of his own accord in 1584. He died in 1586, at the age of ninety. Sir Richard Maitland's claim to notice rests on his valuable collection of Scottish poetry, still preserved in manuscript in the Pepysian Library, Magdalene College, Cambridge. It consists of two volumes, the one a folio, containing 176 pieces, and the other a quarto, containing 96. An edition of Maitland's own poems was published in 1830 by the Maitland Club, a society of literary antiquaries who have assumed his name.

MAIZE, or Indian Corn, the *Zea Mays* of botanists, a monœcious grass of the natural order *Graminaceæ* (see Botany, p. 215), is a native of tropical America, found in its wild state in Paraguay and Chile. Like some others of the same order, its stamens and pistils are in different flowers on the same plant; the stameniferous flowers are borne on the top of the plant, and the pistilliferous ones proceed from the axils of the leaves. The leaves are broad, and are suspended from large rough sheaths which surround the stem. The ripe grains, which are regularly arranged in rows, the one above the other, are compressed at the sides and flattened at the top. Their colour is for the most part pale yellow; some, however, are white, some blood-red, some purple, and some party-coloured. A plant generally has two full ears, varying greatly in the number of grains. Some ears have been known to contain the enormous number of 800 grains. The height of the stems varies from 2 feet to 8 or 10. The floral envelope of the pistil flower is extensively used in Southern Europe for packing oranges and lemons; and the Spaniards of South America contrive, by rolling tobacco into small squares, cut from the thin covers of the grain, to fashion for themselves agreeable cigarettos. Paper of a very excellent quality has been manufactured from the perianths of the maize.

The cultivation of maize has, within the last century, increased to an enormous extent over the American continent, and throughout most parts of Asia, Africa, and Southern Europe. It requires but little labour for its cultivation, and forms an exceedingly wholesome and nutritive diet. Although deficient in gluten, it is nevertheless made into cakes in North America, which are very highly esteemed. Some have advocated the introduction of maize as one of our regular crops in this country; but agriculturists have hitherto been of opinion, that none of its varieties could be ripened in the ordinary seasons of these islands. (See Agriculture, p. 313.) This supposition has recently been proved to be without foundation, by an experiment tried in the summer of 1850, by Mr Keene, on a crop of forty-day maize in St James's Park, London. The seed, which he had introduced from the Pyrenees, was put in the ground on the 24th May, and notwithstanding various drawbacks incidental to the locality, the crop was harvested on the 10th October, "the grain perfectly formed, full and ripe, and the cobs much finer than those grown on the Continent." (*Year-Book of Facts* for 1850, p. 246.) The amount of crop was at the rate of 50 bushels per acre, and the bread formed from it could be had in England at a cost of a halfpenny the pound. It is calculated that 30 acres of average soil, properly drained and sown with maize, would be worth L.400. It is supposed, however, that in the present state of things, maize could be purchased in the home market at a less sum than it could be cultivated, seeing that it can be raised in Ohio at 6d. the bushel of 56 lb., at a good profit. About two-thirds of the maize crop of the Americans are grown for exportation. The quantities of Indian corn or maize entered for home consumption, and chargeable with duty as a British import during the past three years, were as follows:—In 1854, 1,358,380 qrs.; in 1855, 1,224,281 qrs.; in 1856, 1,788,212 qrs. The importation of Indian-corn meal during the same time was as follows:—In 1854, 55,963 cwts.; in 1855, 12,154 cwts.; in

Art. Bil

1856, 7885 cwts. (See CORN LAWS AND CORN TRADE, p. 395. See also a pamphlet entitled *Facts for Farmers: Maize, its Culture and Uses, &c.*, Longman and Co.)

MAJESTY, a title of honour derived from the Romans, among whom *majestas* stood for the highest power and dignity of the people. *Majesty* was ascribed to the dictator, consul, and senate, and to persons or bodies vested with legislative power, in so far as they were the representatives of the sovereign public. At the fall of the republic, the name and dignity of *majesty* passed over to the emperors, and the title of *dignitas* was given to the magistrates. The attribute of *majesty* was not given to kings till much later. It was used first by the German emperors, and was introduced into France under Henry II., and into England under Henry VIII. The Emperor of Austria has the title of *K. K. Majestat* (Kaiserlich-Königliche-Majestat), Imperial Royal Majesty. The Pope conferred the title of *Apostolical Majesty* on Stephen, Duke of Hungary, and on Maria-Theresa; of *Catholic Majesty* on Ferdinand and Isabella of Spain; of *Most Christian Majesty* on the kings of France after Louis XI.; and of *Most Faithful Majesty* on the kings of Portugal after John V.

Majesty is now used conventionally as the title of European emperors and kings, with the exception of the Turkish Sultan, whose title is that of *Highness.*

MAJOR, in military affairs, a field-officer, next in rank above a captain, and inferior to a lieutenant-colonel. The major of a regiment assists the lieutenant-colonel, but has no positive duties in the presence of that officer. An officer must be six years in the service before he can be promoted to a majority. (See ARMY, and COMMISSION.)

MAJOR and *Minor*, in *Music*. See MUSIC, §§ *Intervals, Scales.*

MAJOR, or MAIR, JOHN, a scholastic divine and historian, was born about 1470 at the village of Cleghorn, near North Berwick. After attending for a short time at Christ's College, Cambridge, he entered the university of Paris in 1493. There he studied successively at the colleges of St Barbe and Montaigu, and graduated as A.M. in 1496. Chosen a doctor in 1505, he lectured on philosophy in the latter college, and numbered among his regular auditors the principals Jacques Almain, Robert Cenalis, and Jerome de Hangest. Soon after this, Major seems to have returned to his native country; and in 1518 he is found discharging the office of principal of the university of Glasgow. In his joint capacity of professor of theology, he became in 1522 the preceptor of John Knox. He was promoted to a chair in the university of St Andrews in the following year, and there, in 1525, George Buchanan was one of his pupils. Not long after this, Major removed once more to Paris, but returned to St Andrews in 1530, and became principal or provost of St Salvator's College in 1533. In this office he died about 1550.

The following is a list of Major's principal works:—*In Libros Sententiarum Commentarius*, published in 4 vols., Paris, 1509, 1510, 1517, 1519; *De Historia Gentis Scotorum libri sex*, Paris, 1521; *Commentarius in Physica Aristotelis*, Paris, 1526; and *In Quatuor Evangelia Expositiones Luculcutæ*, Paris, 1529. During his residence in France, Major had imbibed very liberal opinions on civil and ecclesiastical government; and from him it is probable that Knox and Buchanan first received those political principles, which afterwards in their separate spheres they so ably defended. As a writer, he is characterized by small erudition, no independence of thought, and a style bald and inelegant.

MAJORCA, MALLORCA, or MAYORCA, an island belonging to Spain, in the Mediterranean, the largest of the Balearic group, lies between N. Lat. 39. 16. and 39. 57., E. Long. 2. 20. and 3. 30. Its shape is that of a trapezoid, the vertices of the angles being directed to the cardinal points. Its length, from Cap de Pera to Grozer, is about 60 miles; and its breadth, from Palma to Alcudia, about 33. The N.E. portion of the island is very mountainous, the S.W. portion more level; though there occur in the latter isolated peaks of considerable height. The highest peak of the island, Puig Major d'en Torrella, has an elevation of 5120 feet above the level of the sea. The climate of the different districts varies considerably; the western partido, Palma, enjoying a much milder temperature than the central and eastern partidos, Inca and Manacor, as its surface is also more wooded and picturesque. It contains the towns of Valdemoza and Soller, which attract many strangers by the geniality of the air. The heats of summer are tempered by the sea breezes, while the northern coast is visited in winter by very violent gales. The coast facing the continent is generally steep, flatter towards the E., and indented with capacious harbours, that of Palma, the capital, being the largest.

The rocks of this island are limestone, and the mountains present the picturesque appearances usually remarked in that formation. There are quarries of marble, of various grains and colours, those of Santagny, in the partido of Manacor, being especially celebrated; and there are some mines of lead, iron, and cinnabar.

The inhabitants are almost wholly devoted to agriculture, and most of the arable land in the island is under cultivation. The mountains are terraced, and the old pine woods are fast disappearing and giving place to the olive, the vine, and the almond tree, fields of wheat and flax, or to orchards of figs, oranges, &c. Much saffron is also grown. The oil harvest is very considerable, averaging 650,000 gallons yearly. The wines are light, but excellent, especially the Muscadel and Montona. Mules are used in the agriculture and traffic of the island. The oxen are small, but the sheep large and well fleeced. There is abundance of poultry, and of small game. There is not much industry beyond that engaged in or immediately dependent upon agriculture. A good deal of brandy is made and exported. Very superior woollen and linen cloths are made. The silk-worm is reared, and there is a considerable manufacture of silk. Their cabinet-work is celebrated.

In 1846 the population amounted to 179,753. There are two cities, Palma and Alcudia; Palma is an episcopal see. The largest remaining towns are,—Lluchmayor, Campos, Santagny, Inca, and Pollenza, anciently a Roman colony. The inhabitants are industrious and hospitable, and pique themselves much on their loyalty and orthodoxy. Castilian is spoken by the upper and commercial classes; the lower and agricultural employ a dialect resembling that of the Catalans, with whom also their general appearance and manners seem to connect them.

The early history of the Balearic Isles is obscure. The origin of the name itself is doubtful, some deriving it from the Phœnician god Bal (Baal), others connecting it, through the Greek, with their celebrated skill in the use of the sling. The Balearic slingers were useful auxiliaries to the Carthaginians, and contributed to the victories of Trebia, Thrasymenus, and Cannæ. But it was their piracies which drew on them the Roman vengeance. About 123 B.C. they were subjected by Q. C. Metellus, who established a Roman colony at Pollenza, introducing Iberians, and erecting an aqueduct 6 miles in length, the remains of which still exist. Metellus also introduced the Roman tongue, and the cultivation of the olive. By the Romans the two principal islands were called Major and Minor, whence their modern names. In A.D. 423 they were taken possession of by the Vandals, and in 798 by the Moors. The Balearic Isles became a separate Moorish kingdom in 1009; which, becoming extremely obnoxious for piracy, was the object of a crusade directed against it by Pope Pascal II., in which the Catalans took the lead. This expedition was frustrated at the time, but was resumed by Don Jaime, King of Aragon, and the Moors expelled in 1232. During their occupation, the island was populous and productive, and an active commerce was carried on with Spain and Africa. Don Jaime conferred the sovereignty of the isles on his third son, under whom and his successors they formed an independent kingdom up to 1349. Thenceforth their history is that of Spain. In 1521 an insurrection of the peasantry against the nobility, whom they massacred, took place in Majorca, and was not suppressed without much bloodshed. In the war of the Spanish succession all the islands declared for Charles; the Duke of Anjou had no footing anywhere save in the citadel of Mahon. Minorca was reduced by Count Villars in 1707; but it was not till June 1715 that Majorca was subjugated. When the French invaded Spain in 1808, the Mallorquins did not remain indifferent; the governor, D. Juan Miguel de Vives, announced, amid universal acclamation, his resolution to adhere to Ferdinand VII. At first the Junta would take no active part in the war, retaining the corps of volunteers that were formed for the defence of the island; but finding it quite secure, they transferred them successively to the Peninsula to reinforce the allies. Such was the animosity excited against the French when their excesses were known to the Mallorquins, that some of the French prisoners, conducted thither in 1810, had to be transferred with all speed to the island of Cabrera, a transference which was not effected before some of them had been killed.

MAKALLAH or Macullah, a town on the S. coast of Arabia, N. Lat. 14. 31., E. Long. 49. 6., 300 miles E.N.E. of Cape Aden, and about the same distance S. of Mareb. The town stands on a narrow projecting ledge of rocks, in the centre of a bay of the same name. Its appearance, as seen from the sea, is very grand, and it is defended by six square towers on the height above, as well as by walls. The bay affords very good shelter for vessels, being protected on the S.E. by a promontory bearing the same name, at the distance of 4 miles; and towards the W. there is a reef forming a secure harbour, much frequented by coasting vessels. Immediately behind the town rise a series of limestone cliffs to the height of 300 feet, beyond which is a lofty mountain called Jebel Gharrah, 1300 feet above the sea. The town is chiefly composed of huts, along with a few stone houses and two mosques. A considerable traffic is carried on here; for, besides supplying vessels with provisions, it exports gum, hides, senna, &c.; and imports cotton, lead, and iron from Bombay, and sheep, calves, honey, and slaves from Kosseir and Berberah. The inhabitants of this town are very varied; for besides the native Arabs, who do not comprise more than half of the population, there are Banyans, in whose hands most of the trade with India is; Karachies from the Persian Gulf; Sahawili from the E. coast of Africa; and Somali from the coast opposite Aden. Pop. estimated at about 4500.

MAKO, or Makovia, a market-town in East Hungary, in the palatinate of Cnasad, on the Maros, 9 miles W. by N. of Cnasad, and 21 miles E.S.E. of Szegedin. It is the seat of a bishop; and has a Roman Catholic church, a Greek church, a Protestant church and gymnasium, and a Jewish synagogue. The town contains a court-house and county buildings, and a handsome barracks recently erected. The neighbourhood is very fertile, producing corn and wine, and affording excellent pasturage for cattle. Many of the inhabitants subsist by river fishing. A considerable trade is carried on in the products of the vicinity. Pop. (1851) 22,611, of whom more than half were Protestants, and a considerable number Jews.

MAKRI, Macri, or Makry, a seaport-town on the S.W. coast of Anatolia, Asiatic Turkey, N. Lat. 36. 37., E. Long. 29. 9., being 52 miles E.N.E. of Rhodes, and 125 S.E. of Smyrna. The modern town, which consists of a collection of about fifty wretched huts, is built on the site of the ancient Telmessus, in the midst of a landscape of unrivalled beauty, although the town and neighbourhood are extremely unhealthy. There are still to be seen the remains of an ancient theatre in very good preservation, besides many tombs of various ages. The harbour, anciently called *Glaucus*, is very good, being sheltered from the sea by the island of Cavalière, and running into the land to the distance of 12 or 15 miles. It is at this place that travellers from Constantinople to Syria embark, and there is generally a great number of vessels in the bay. The trade of the town is extensive, and consists of wood, tar, honey, cattle, salt, and nuts, with many of which articles it supplies Rhodes. Provisions in this town are easily and cheaply procured.

This is also the name of a seaport in Rumili, 75 miles S.W. of Adrianople. The harbour is defended by a castle, and the town is the residence of a Greek bishop. It is the capital of a district, and its population is about 3000.

MALABAR. This tract of country extends along the western coast of India, from Cape Comorin to the River Chandragiri, in N. Lat. 12. 30. The British province of Malabar is a particular portion of this tract, which is situate between the 10th and 13th degrees of N. Lat. To the N. it is bounded by the province of Canara, to the S. by the rajah of Cochin's territories, to the W. by the ocean, and to the E. by the chain of the Western Ghauts, below which the country lies, extending about 200 miles along the sea-coast. The country may be divided into two portions, the first of which borders the sea-coast, and consists of a poor sandy soil, seldom above 3 miles wide, and in general not so much. Low branches of hills extend from the Ghauts to a considerable distance to the westward, and sometimes even to the sea. The strip of country bordering upon the sea is well adapted for the cultivation of rice; and it is remarkably intersected by inlets of the sea, which often run for great lengths parallel to the line of coast, receiving the various mountain streams, and communicating with the ocean by different narrow and shallow openings. In other places, the fresh water, as it descends from the mountains into the low lands within the downs upon the sea-coast, in the rainy season, totally overflows them, as the water has no issue, and must consequently stagnate until it evaporates. By this natural irrigation the lands are fitted for some particular qualities of rice. There are a few mountain streams and rivers; and the distance of the mountains from the sea is too inconsiderable for the formation of any large river. By far the most extensive portion of Malabar lies in the vicinity of the Ghaut Mountains, and consists of low hills, separated by narrow valleys, which are in general extremely fertile, being the receptacles of the fine particles of mould carried down from the hills. The hills are seldom of any considerable height, and have mostly level summits, which are bare in many parts, especially towards the N., and expose to the view large surfaces of naked rock, with remarkably steep sides. They are in general very industriously cultivated; their sides, which possess the best soil, being formed into terraces. The valleys are in most cases watered by rivulets which carry off the superfluous water, and where there is no issue, it overflows the adjacent lands. The upland is barren, and the cultivation much neglected; and it is in the valleys and extensive ravines, and upon the banks of the rivers, that the inhabitants chiefly reside. Dr Buchanan mentions in his *Journey from Madras*, &c., vol. ii., that some parts of the country which he passed through in this province were the most beautiful he had ever seen, being equal to the finest parts of Bengal, but the trees were loftier, and the palms more numerous. In many places the rice grounds are interspersed with high swells, that are crowded with houses; whilst the view to the N is bounded by naked rocky mountains, and to the S. by the lofty forests of the Travancore Hills. The climate is moist; the low country of Malabar, as well as the whole region which lies under the Western Ghauts, becomes excessively hot in the month of February; and the vapours and exhalations are so thick, that it is difficult to distinguish objects at the distance of even 5 miles. These vapours become visible around the mountains, where the cold is very severe. The moisture collected increases with the heat; and in March and April a prodigious quantity is accumulated, and floats in the atmosphere, sometimes ascending nearly to the tops of the mountains, where it is checked or condensed by the cold; but, descending immediately after, it is again rarified by the heat of the lower atmosphere into vapour, before it reaches the earth. At the setting in of the western monsoon, the whole is condensed into rain, which falls very heavily, partly in the low country, and partly in the mountains; and a small portion escapes and is blown across Mysore. These heavy rains serve to bear away the soil, and leave nothing but loose stones and sand upon the hills. The country abounds in lofty forests, which are sometimes intermixed with corn fields and plantations of fruit trees. The teak is produced in great abundance, mostly about Manarghaut; but it is too remote from any navigable river to be transported with a profit from the place of its growth. Sandalwood is also exported from Malabar, though it is not the produce of the country; at least such as is found within the limits of Malabar is not of a good quality, being entirely devoid of smell; but, growing as it does immediately to the eastward of the Western Ghauts, all that is produced towards the sources of the Cauvery naturally comes to Malabar, which affords the nearest ports that can be found for its exportation. The palm is produced in the greatest abundance about Palighaut, and, with proper care, an excellent spirit might be extracted from it. These forests, unlike others in India, were the private property of the land-holders, who exercised the right of selling and mortgaging the trees to Moplay merchants. The demand for teak timber was so great that the woods were fast becoming exhausted. With a view to the restoration of these forests, extensive tracts of waste land have been converted by the government into teak plantations. In the latter part of 1843, and the spring of the following year, no less than 50,000 young trees were planted in these nurseries. Cocoa-nut trees abound in the province. Black pepper is produced abundantly in Malabar, and forms the chief export by Europeans, who usually purchase about five-eighths of all that is produced, and carry it principally to Europe directly, or to Bombay and China. The remainder is chiefly exported by native traders to the Bay of Bengal, Surat, Cutch, Scinde, and other countries in the N.W. of India; and a considerable quantity finds its way to the Arabian ports of Muscat and Mocha, and to the British port of Aden. They use scarcely any horses or asses in Malabar; and such as are required for the use of the inhabitants are imported from the east. They have a small breed of cattle and buffaloes; but even these are but little used in the transportation of goods, which are usually carried by porters. Poultry have been introduced into the country by the Europeans; and common fowl may be had in abundance. Until a recent period slavery existed in Malabar; but in 1843 a legislative enactment was passed by the government, by the provisions of which slavery has been abolished throughout the whole extent of our eastern possessions. The country is distinguished by the neatness of its villages, which are superior to any in India, being built of mud, neatly smoothed, and either whitewashed or painted. Their picturesque effect is heightened by the beauty and elegant dresses of the Brahmin girls. The villages, as well as the bazaars, are the work of foreigners, the aboriginal natives of Malabar living in detached houses surrounded with gardens. The higher ranks use little clothing, but are remarkably clean in their persons; and all ranks are free from cutaneous distempers, excepting the very lowest castes.

The country being intersected by many rivers, and bounded by a high wall of mountains, was protected by these natural obstacles against the torrent of Mohammedan invasion which desolated other parts of India; and it was not till 1766, when it was invaded by Hyder Ali, that it was subjected to a foreign yoke. Hence the original manners and peculiar customs of the Hindus have been preserved here in much greater purity than in other parts of India. Besides the Hindus, who form the great proportion of the inhabitants, the population consists of Moplays or Mohammedans, Christians, and Jews. The Hindus are divided into the following castes, namely, Namburies or Brahmins; the Nairs of various denominations; the Teers, or Tiars, who are cultivators of the land, and freemen; the Malears, who are musicians and conjurors, and also freemen; and, lastly, the Patiars, who were slaves or bondmen. Of these castes, the most remarkable are the Nairs, the pure Sudras of Malabar, who all lay claim to be born soldiers, though they are of various ranks and professions. There are altogether eleven ranks of Nairs, who form the militia of Malabar, under the Brahmins and rajahs. They are proud and arrogant to their inferiors; and in former times a Nair was expected instantly to cut down a cultivator or fisherman who presumed to defile him by touching his person, or a Patiar who did not turn out of his road as a Nair passed. It is a remarkable custom amongst this class, that a Nair never cohabits with the person whom he calls his wife. He gives her all proper allowances of clothing and food; but she remains in her mother's or brother's house, and cohabits with any person or persons she chooses, of equal rank; so that no Nair knows his own father; and the children all belong to the mother, whose claim to them admits of no doubt. This state of manners also prevails in the neighbouring countries of Travancore, Bednore, and Canara.

As in Malabar the ancient Hindu state of property and manners prevails, almost the whole land, cultivated and uncultivated, belongs to individuals, and is held by a right which conveys a full and absolute property in the soil. There are many traditions and conjectures respecting the origin of landed property in those countries; and upon this subject a very full detail will be found in Mr Thackeray's report on the land tenures and assessments in Malabar, in the *Fifth Report of the Select Committee on India Affairs*, p. 799, in which he, along with Colonel Munro and others, strongly contends, that in the southern parts of India, namely, in Malabar, Tanjore, Trichinopoly, &c., the private right of property in the soil has been established from time immemorial. "The occupants of the land," says one of the collectors of the revenue in Southern India, "by whatever name distinguished, have the right of selling, bestowing, devising, and bequeathing their lands, in the manner which to them is most agreeable." The succession to property, in consequence of the extraordinary customs of the Nairs, depends on the mother, about whom there can be no mistake, though the father is frequently uncertain.

Christianity appears at a very early period to have made considerable progress on the Malabar coast; and there is a greater proportion of persons professing that religion in this than in any other part of India. Three ecclesiastical chiefs—two appointed by the Portuguese church at Goa, and one by the see of Rome—rule over this establishment, besides the Babylonish bishops who preside over the Nestorian community. At the time of Buchanan's visit 44 churches composed the Nestorian communion, which had been reduced from 200,000 souls, its amount before the arrival of Vasco de Gama, to about 40,000. The total number of Christians on the Malabar coast, including the Syrians or Nestorians, is computed to amount to 200,000, of whom 90,000 are settled in Travancore. The Jews are estimated at 30,000.

It is supposed that Malabar was, at a very early period, conquered by a king from above the Ghauts. The Nairs may have been established at the same time by the conqueror, or called in by the Brahmins, as a military body, to support the government. In process of time they obtained settlements in the land; and the chiefs, taking every opportunity to aggrandize themselves, became rajahs, and from a remote period continued to govern Malabar like independent princes until Hyder's invasion in 1760. Tradition, and the general opinion of the inhabitants, contradict the notion that any land-tax existed in Malabar prior to that event. No conclusive evidence is supplied on this subject by the doubtful analogies of the neighbouring states, in some of which, such as Travancore, no land-tax was said to exist, whilst in Canara a regular land-tax has been imposed for centuries. There does not seem to have been any urgent necessity for the establishment of a general land-tax, as there was no army besides the militia, nor indeed any expensive establishments. Hyder subdued the country in 1761, and expelled all the rajahs, except such as conciliated him by immediate submission. Disturbances were occasioned by these proceedings; but he succeeded in establishing his authority, and in 1782 appointed a deputy, who made still further progress in subduing and settling the country. In 1788 Tippoo, his son, proposed to the Hindus to embrace the true faith, and began by levying contributions on his infidel subjects, and forcibly circumcising many of the Brahmins, Nairs, and others. This produced a serious rebellion, which, however, was soon quelled by his vigorous administration; and in the meantime the country was laid waste by these tyrannical proceedings. On the breaking out of the war between Tippoo and the British in 1790, the refractory rajahs and Nairs, who were leading a predatory life in the jungles, were encouraged to join the Company's army. After the war, they were reinstated in their authority; but they made such large claims to independence, whilst they failed at the same time to fulfil their engagements for the payment of the revenue, and were also so tyrannical in their proceedings, that they were finally deprived of all authority, and allowed one-fifth of their revenues for the support of their dignity. Many of them, in consequence, had recourse to rebellion; but they were put down by a military force, and some of them punished. Since this period, under the management of the British collectors of revenue, the country exhibits comparative tranquillity, and is said to be advancing in prosperity. The population, according to the census which was taken in 1850, amounted to 1,514,909.

Under the name of Malabar is distinguished a large tract of country, extending along the western coast of India from Cape Comorin to the River Chandragiri, in N. Lat. 12. 30.; and the term is frequently erroneously applied to the whole country from Bombay to the southern extremity. The above account applies chiefly to the British province of that name. (E. T.)

MALABAR POINT, a promontory of Hindustan, on the S.W. extremity of the island of Bombay, remarkable for a cleft rock, in great repute for its sanctity amongst the numerous Hindus who resort thither for the purpose of being purified from their sins, which is effected by passing through the aperture, which is of considerable elevation, being situated amongst rocks of difficult access that in the stormy season are incessantly washed by the billows. In the vicinity are the ruins of a temple, said to have been blown up by the Portuguese; and a beautiful Brahmin village, built round a fine tank of considerable extent, with broad flights of steps down to the water.

MALACCA, an extensive region, situate in Southern India, consisting of a large peninsula, connected by the Isthmus of Kraw, about ninety-seven miles in breadth, with the province of Tenasserim to the N., whilst on all other sides it is bounded by the Eastern Ocean, having on the W. the Indian Ocean and the Straits of Malacca, which separate it from Sumatra, and on the E. the Gulf of Siam and the Sea of China. It extends from the 1st to the 12th degrees of N. Lat., and from the 98th to the 104th degrees of E. Long., and is 775 miles in length by 125 in average breadth. The country is a long, narrow strip of land, traversed by a chain of lofty mountains, and covered with extensive forests and marshes, so that it is very difficult to penetrate into the interior. A range of extremely bleak mountains, running through it from one extremity to the other, gives rise to innumerable streams, the courses of which, from the proximity of the mountains to the sea, are short, and they are obstructed at the mouths by bars and sandbanks, so that they cannot be ascended by vessels of any size. At the southern extremity of the continent are the islands of Bintang, Batang, and Singapore, with many others, so thickly clustered together, that they are only separated from the continent by narrow straits, and seem to be a prolongation of the land. On the W. coast also there are numerous islands, amongst which may be mentioned Pulo Pinang, or Prince of Wales Island.

The soil is not remarkable for its fertility, though, like other Malay countries, the coast is well covered with wood, and exhibits a great extent of verdure; but the teak tree has never yet been discovered in these forests. The fruits are excellent and plentiful; but grain is not produced in sufficient quantity, and is therefore imported from Bengal and Sumatra. The jungles, from their density and great luxuriance, are impervious to animals, and game is in consequence scarce. From the rivers, as well as the sea, the inhabitants derive a plentiful supply of fish.

The political state of Malacca has been subject to many revolutions, having been occasionally dependent on Siam when that monarchy was in the height of its power, and when its supremacy was owned by the whole peninsula. But since the Siamese have yielded to the increasing power of the Burmans, all the southern portion of the peninsula has shaken off the yoke, and the northern states pay only a moderate tribute. The whole of the sea-coast, from that latitude to Point Romania, is still possessed by the Malays, who are mixed in some places with the Buggesses from Celebes, and who have still a small settlement at Salengore. The northern and inland parts of the peninsula are inhabited by the Patany people, who appear to be a mixture of Siamese and Malays, and who inhabit independent villages. The Negro race is found in the interior amongst the aboriginal natives. The great majority of the inhabitants are, however, of the Malay race, who are well known and widely diffused amongst all the eastern islands. The origin of this remarkable race is not very distinctly known. They are understood, however, not to be natives of this country, but to have come originally from the district of Palembang, in the interior of Sumatra, situate on the banks of the River Malaya. Having crossed over about the end of the twelfth century to the opposite continent, they, in 1252, founded the city of Malacca. They are of a daring, restless, and intrepid disposition; their character forming in this respect a striking contrast to that of the timid inhabitants of Hindustan. They are brave in war, but ferocious and vindictive, merciless to enemies and strangers, and capricious and passionate even to friends. They are proud and irascible, carrying the point of honour to excess, with a quick sensibility to the slightest insult, which drives them to a degree of fury bordering on desperation; and it is by a series of what they, in their overwrought fancies, consider to be insults, that they are excited to a state of frenzy which ends in that act of wild atrocity known by the name of "running amok," from the word *amok*, signifying kill, kill. The Malay, when he has resolved on this desperate step, proceeds still farther to inflame his passions by taking a dose of opium, when he throws loose his black hair, and drawing his deadly crease, rushes into the streets, thirsting for vengeance, and crying "kill, kill," slays every one whom he meets in this furious mood. But it has been found that these unruly passions, which often broke out into violent excesses under the tyrannies of their Dutch rulers, were greatly allayed by kind treatment; and that the Malay, in these circumstances, was transformed into an entirely different character, displaying gratitude, affection, fidelity, and higher sentiments of honour than are found amongst any other class of natives in India. Those Europeans who have engaged them as servants, and who have treated them well, inform us that they found them faithful and attached domestics. The free Malays are an intelligent, active, industrious body of men, engaged, like the Chinese, in foreign trade. They have always addicted themselves to seafaring pursuits, and to piracy, which they follow as if it were a lawful trade; and hence they are the terror of the effeminate Asiatics. Their prows are many of them fine vessels, and navigated with skill; but the Malay, though in general a bold and hardy mariner, is apt to sink under a continuance of cold or bad weather, even sooner than the feeble but more docile lascar of Bengal. Though they have been more circumscribed in their piracies by the maritime superiority of the Europeans in the eastern seas, and no longer retain those daring habits which rendered them the scourge of the peaceful trader, they still carry on petty depredations; and trading vessels are sometimes cut off, and their crews murdered with every circumstance of atrocity.

The government of the Malays is a rude description of monarchy, with a turbulent aristocracy, or something like the principles of the feudal system. The head of the government is a rajah or sultan, a name assumed from the Arabians; and under him a certain number of nobles, with their train of vassals. But in practice there is no regular system of subordination, the sultan trampling on the chiefs and the people, and they again rebelling against his authority; so that there is little else amongst them but violence and disorder, which contribute to nourish their ferocious habits.

The language of the Malays has obtained very general currency in several states upon the continent, as well as amongst the eastern islands, though it has gained no footing in the interior of Hindustan. On the sea-coast, and at the mouths and on the banks of navigable rivers, it is the medium of commercial and foreign intercourse; and the currency which it has acquired may be ascribed partly to the commercial and enterprising character of the people, who, by their mercantile habits, or the power of their arms, have established themselves in every part of the archipelago, and also to its own valuable qualities of simplicity in the structure, and even of pronunciation. In writing it, they use the Arabic character, with the addition of six other letters. The Malays have few books in their language, and these consist chiefly of transcripts and versions of the Koran, commentaries on the Mohammedan law, and tales in prose and verse, many of them translations of the popular tales current in Arabia, Persia, India, and the neighbouring island of Java. They have also some historical compositions.

The Malayans profess the Mohammedan religion. Until the year 1276 they were pagans, or followed some corrupted form of Hindu idolatry. Sultan Mahommed Shah, who ascended the throne in the thirteenth century, was the first prince who, by the propagation of this faith, acquired great celebrity during his long reign of fifty-seven years. His dominion extended over the neighbouring islands of Lingen and Bintang, together with Johore, Patany, Quedah, and Pera, on the coasts of the peninsula, besides several districts in Sumatra, all of which acquired the appellation of Malaya. During part of the fifteenth century, Malacca was under the Siamese sovereigns. In 1509 Sultan Mahmud repelled the aggression of the King of Siam; but in 1511 he was conquered by the Portuguese under Albuquerque.

MALACCA is the capital of the country of Malacca, and is situate on the straits of the same name, near the southern extremity of the Malay Peninsula. The town is large; many of the houses are built of stone; and there are several spacious and handsome streets. But that part of it inhabited by the natives consists of bamboo and mat huts. Since the formation of the British settlement at Pulo Pinang, or Prince of Wales Island, its commercial importance has declined. The surrounding country is fertile and beautiful, being finely diversified for eight miles round with hill and dale; and beyond that distance it is rendered impracticable by woods and morasses. There is a good roadstead for large ships about a mile and a half from the place; but the entrance to the river is rendered intricate by a bar, over which boats cannot pass before quarter flood, nor after last quarter ebb, without much difficulty. Under the lee of the island, near to the fort, there is a harbour, where, in the south-west monsoon, vessels of light burden may be secured. On the southern side of the river is a fort, the walls of which are in a ruinous condition. The chief imports are grain, which is brought in considerable quantities from Bengal, Java, and Sumatra, opium, piece-goods, silks, and dollars. The exports are chiefly tin, pepper, sago, canes, elephants' teeth, biche-de-mer, and some gold dust. Fruits and vegetables are abundant; and there is also plenty of buffaloes, hogs, poultry, and fish, at moderate prices, though sheep and bullocks are scarce. Malacca was founded about the year 1252; and in 1508 it was first visited by the Portuguese, who, on a quarrel which broke out, were arrested by the king, and being thrown into prison, several of them were put to death. Albuquerque, the renowned Portuguese commander, immediately declared war against this eastern prince; and, after an obstinate contest, stormed the town of Malacca, which became one of their principal settlements, and the key of their trade with the seas beyond India. In 1605 it was attacked by the Dutch, who destroyed a Portuguese fleet in the roads, but failed to take the place. In 1640, however, they reduced it after an obstinate resistance, and retained it till the year 1795, when it was subjected by a British force, but was restored at the peace of Amiens. It was afterwards recaptured by the British, but once more restored to the Dutch in 1818, after the general pacification. In 1824 the town, and a district containing an area of about 1000 square miles, were finally transferred to the British among the cessions made by the King of the Netherlands, in exchange for the British possessions on the island of Sumatra. E. Long. 100., N. Lat. 5. (E. T.)

MALACHI, the last of the minor prophets, flourished contemporarily with Nehemiah; and from various coincidences in his prophecy with Nehemiah chap. xiii., it may be concluded that they acted together in the work of political and religious restoration. His name (*My Angel*, or rather *Angel of Jehovah*) has by some been regarded as only an official title, and, in absence of evidence in regard to his personal history, Ezra, Nehemiah, Mordecai, and even an incarnate angel, have been put forward as authors of the book. In the same way, all Scripture history might be unsettled. That Malachi flourished later than Zechariah is sufficiently evident from the fact that he is not mentioned along with that prophet in the book of Ezra; and from internal evidence it is plain that he lived to see a more thorough restoration of the Jewish worship than Zechariah was privileged to see. He even lived to see the restored worship decline; and amid the decay of morals he prophesied the advent of the forerunner of the Messiah. The canonicity of this book is undoubted. Special expositions of it have been written,—among others, by Venema, Bahrdt, Faber, and Fischer.

MALAGA, the third seaport of Spain, and capital of the province of the same name in Granada, is situate on the Mediterranean, in 36. 43. N. Lat., 4. 26. W. Long., 65 miles E.N.E. of Gibraltar, and 253 S. by W. of Madrid, at the extremity of a fine large bay, and on a plain bounded by lofty hills on the N.E. and N.W. In the clearness of its sky, which a cloud rarely obscures, and the beauty of its bay, it resembles Naples, to which it has sometimes been compared. The scanty river Guadalmedina flows here into the sea after receiving the Guadalhora; and the town lies principally on the left bank of the former; the districts of La Trinidad and Perchel, on the latter, being little more than a suburb. Sheltered on the E. and W., the climate is very salubrious. There are no endemic diseases, although, like other Mediterranean seaports, it has suffered much at various times from yellow fever, &c. The streets near the sea are spacious and comparatively modern, giving the town a fine appearance from the bay; the other streets are narrow and ancient, still remaining almost as they were when the town was taken from the Moors in 1487. There are various *plazas* and *paseos*. In the Plaza de Riego was erected, in 1842, a monument to the unfortunate Torrijos. The edifices most worthy of note are,—the cathedral, the custom-house, and the bishop's palace. The cathedral was commenced by Diego de Siloe, architect of that of Granada, in 1526, in the Greco-Roman style, which he introduced, and was continued by various architects till its completion in 1782 by Jose Bada. It exhibits, in consequence, a singular mixture of styles; but the general effect of the interior is pleasing, and the exterior would be imposing were it not marred by the crowd of shabby houses about it. The custom-house is a stately and spacious edifice, built partly on the site of the Moorish fortress Alcazaba, to the N.E. of the town. It was begun in 1791, but the work being interrupted by the war, was not finished till 1829. The bishop's palace, which contains also the offices, archives, and library of the see, was erected in 1772, at the expense of the then prelate, Don José Franquis. Of more ancient buildings, the two Moorish fortresses, Gibralfaro and Alcazaba, on a hill to the N.E., deserve mention. The former, which is extensive, and still in good preservation, was built A.D. 787, by Abdelrhaman I., King of Cordova, on the site of a more ancient tower, and offered an obstinate resistance to the Catholic kings. Of Alcazaba the remains are trifling. On the whole, Malaga, though not a handsome town, has a more modern aspect than most Spanish towns. An object of special attraction to visitors is the English burying-ground, situate about a mile from the city, to the E. of the Alcazaba, beautifully laid out, and at much expense; the soil being terraced, irrigated, and planted with cypresses. To complete the description of the port, it must be added, that though there is no regular harbour, vessels receive shelter from a mole about 884 yards in length, at the extremity of which is a lighthouse with a rotatory light, standing about 130 feet above the sea-level. To prevent the silting up of the harbour so formed, two smaller lateral breakwaters were subsequently formed. The commencement of the former work dates from 1588; but it did not reach its present length before the end of last century. The harbour is capable of containing several hundred merchant vessels; and ships of the largest burden can approach the quays.

The commerce of Malaga consists chiefly in the productions of the province, the staple being wine and raisins. The latter are made from the June harvest, and largely exported. The quality has of late years much improved, and they boast that their raisins quite equal those of Valencia. There is a second and third harvest, producing wines exported chiefly to the United States and South America. "Formerly vast quantities of very inferior quality were manufactured, but were found unsaleable even to the Americans; they have therefore been obliged to change the system, and the whole class is much improved in consequence." (*Widdrington.*) The Muscatel, Lachryma Christi, and Vino de Guindas (so called from its being flavoured with cherries), are the best wines. The *lagrimas* is made from the droppings of the large white Muscatel grapes unpressed. The vineyards around Malaga are estimated to produce annually, of all sorts—sweet, dry, and luscious—between 30,000 and 40,000 butts, of which nearly 27,000 are exported. Olive oil, saffron, soap, and some other articles, are also exported. The most active period in the port is from the 15th of August to the end of October, the exportation of the new fruits going on. This period is called the *Bendejà*. The harbour is then filled with vessels of all sizes and flags, and the streets choked with cars and wagons bringing in the produce of the fields. Besides the vines and cereals, the province boasts many tropical products: the sugar-cane, called *indigenous*, is grown along the E. coast from Torrox to Velez Malaga; the Malaga yam or batata, oranges, lemons, figs, &c., are cultivated. Silk is reared, and cochineal to some extent, though the exposure to the N.W. winds is not favourable to the necessary plantation of cactus. Were the land not so heavily burdened, and were a better system of agriculture adopted, this province would be rendered infinitely more productive. Sheep, hogs, and goats, are reared in the mountainous ranges. The horses are not so good as those of Lower Andalusia. Formerly, in the oak woods around Malaga, a vast quantity of hogs were reared, and bacon exported; but these woods have given place to the vine, olive, &c., which clothe the hills to their summits. There is abundance of small game, hares, rabbits, partridges, and quails, in their season.

There are in the town, manufactories of soap, leather, and linen cloths; but by far the most important and remarkable are the iron foundries, particularly that called La Constancia, which took its rise, in 1826, from the discovery of the abundant mines of Sierra Blanca, near Marbella. A company was formed, and workmen brought from Biscay, Piedmont, Belgium, and France; but after numerous and costly endeavours, it was found that the result did not cover the outlay, and the works were on the point of being abandoned, when one of the directors, Don Manuel Heredia, took the whole management and burden upon himself, introduced the English method of smelting the iron with coal, and brought over a number of English workmen. The iron is made at Marbella, and brought to Malaga to be refined. There are two foundries in Malaga for this purpose: the tall chimney of one is a conspicuous object from the bay. Including the Marbella works, there are about 3000 operatives employed in this manufacture. The mines are very productive, and might supply all Spain with iron. There are, besides, in the province eighteen mines of lead and some of graphite. In Las Chapas, district of Ogen, argentiferous lead ore has been discovered, but in too small quantities. Copper and nickel are also found. There are quarries of marble and various other stones, among which the famous stone of Mijas, a kind of opaque agate. There is an annual fair in Malaga, commencing on the 8th of September, and lasting eight days, held in the Alameda (shaded walk) de Olletas. It is not much frequented.

Malaga is the *Malaka* of Strabo, a word which has been variously derived. By some, through the Phœnician, it is referred to the quantities of salted fish for which it was celebrated. Wilh. Humboldt says it is of Basque origin, meaning the slope of a hill. At all events, the foundation of the town is universally attributed to the Phœnicians. From the Carthaginians, in whose hands its commerce flourished, it was wrested by the Romans, who conferred on it the title of *Civitas Federata*. The Roman remains found in the city and environs are innumerable. (*Ponz. Viage.*) It was taken possession of by the Arabs, without opposition, after the disastrous battle of Guadalcte, and is mentioned as one of the most important cities of Andalusia in the division made of Spain by Jusuf, in 747. It was attached to the caliphate of Cordoba; but on the fall of this caliphate with the dynasty of Omia in 1015, it became the seat of an independent kingdom, with various fortune. In 1487 it was wrested from the Moors by Ferdinand and Isabella, after undergoing all the horrors of a protracted siege. In 1810 the city suffered much from the French general Sebastiani having offered an ineffectual resistance. In 1834 it was the theatre of a melancholy tragedy. General Torrijos and forty-nine Liberals suffered military execution on the 11th of December in that year. A monument has since been erected to their memory. The population of Malaga in 1847 amounted to 68,577.

MALAGRIDA, Gabriel, an Italian Jesuit, was born in 1689. Having entered the Order of Jesus, he was despatched by that fraternity to Lisbon. There, in process of time, he raised himself to notoriety by his pretensions to sanctity and supernatural intercourse with heaven. Yet this very prominence subjected him to a greater amount of the suspicion with which the government of Portugal at that period regarded the Jesuits. Accordingly, in 1758, Malagrida was apprehended on the charge of being privy to a conspiracy against the crown. Instead of being arraigned before a civil tribunal, he was delivered into the power of the Inquisition. Accused before that court of having written two books relating his interviews with the Virgin Mary and her mother St Anne, Malagrida was condemned as a heretic, and was burnt at the stake in September 1761.

MALAR, a lake of Sweden, stretching westward from the Baltic, and lying between the laens of Westeras, Upsala, Nyköping, and Stockholm. Unlike most other lakes, it is made up of a number of smaller lakes united by channels, so that, although its length is about 78 miles, and its average breadth 12, there is scarcely throughout this whole extent a sheet of water of a mile square. It is studded with islands to the number of about 1300; and it sends a great many branches into the land, all of which are navigable. The level of the water is nearly the same as that of the Baltic, and numerous steamers ply upon it to and from Stockholm, which is situate at the eastern extremity on both sides of the lake. The convenience of such a sheet of water for navigation is very great, and its advantages have been further increased by the Södertelge and Strömsholms canals. The former of these is about two miles long, and opens up the communication with the Baltic; while the latter extends from the western end of the lake, for 50 miles into the interior, in a northerly direction, and terminates in the region of the mines in the Lake of Barken. The scenery of the banks is very beautiful, and there are many villas and country seats belonging to the inhabitants of Stockholm.

MALAY PENINSULA. See Malacca.

MALCOLM, Sir John, G.C.B., the son of a farmer, was born in May 1769, in the parish of Westerkirk in Dumfriesshire. At the age of twelve he received a cadetship in the Indian army; and in April 1783 landed at Madras, and joined his regiment at Vellore. For some time he was noted among his comrades for little else than a youthful light-heartedness, which gained for him the epithet of the "Boy Malcolm." But when a war with Tippoo Saib broke out in 1790, Malcolm, ambitious of obtaining a diplomatic office, began to improve his imperfect education by the study of the languages, especially Persian. Accordingly, in 1792, when stationed before Seringapatam, he was appointed to the staff in the capacity of Persian interpreter. Forced by ill health to leave for England in 1794, he employed his leisure in cultivating those literary talents which contributed in no small degree to his subsequent eminence. On his return to India in 1796, Malcolm became secretary to Sir Alured Clarke, commander-in-chief at Madras, and afterwards to his successor, General Harris. In 1798 his knowledge of the languages and political state of India induced Lord Wellesley, the governor-general, to appoint him assistant to the resident at Hyderabad. The duties of this office he was soon summoned to discharge by the rising of a mutinous spirit among the French troops in the pay of the Nizam. Displaying great coolness and decision, he surrounded the malcontents with a body of 1500 horse, and, without firing a shot, forced them to lay down their arms and disperse. In 1799, beneath the walls of Seringapatam, began his intimacy with Arthur Wellesley, which in a short time ripened into a lasting friendship. During the same year he acted as secretary to the commission appointed to settle the Mysore government. About this period Lord Wellesley held the current opinion that Bonaparte's movements in Egypt and Palestine tended towards an invasion of the British possessions in India. Accordingly, he despatched Malcolm on an embassy to Persia for the purpose of forming an alliance with that country. Arriving at Teheran in December 1800, Malcolm so influenced the Persian courtiers by his liberality and imposing address, that a treaty was struck, in which Persia agreed to repel the French should they ever attempt to enter her boundaries. At the close of the Mahratta war in 1804, when General Arthur Wellesley had succeeded, by a rapid succession of brilliant victories, in restoring the peishwa to his ancient supremacy, Malcolm was employed in negotiating with the conquered enemy. In 1807 and 1810 respectively, he was once more sent as ambassador to Persia; but beyond the information which he afterwards incorporated in his history of that country, his missions were attended with no substantial result. Malcolm sailed for England in 1811, and shortly after his arrival in 1812 he received the honour of knighthood. His interval of leisure he devoted to the composition of the *History of Persia*, a work which was published in 1815 in 2 vols. 4to. No sooner had he returned to India in 1817, than he was nominated the governor-general's political agent, and brigadier-general under Sir T. Hislop. In this latter capacity he served against the Mahrattas and the Pindarees, and bore so distinguished a part in the victory of Mehidpoor, that he shared in the thanks that were awarded to his commander by the British Parliament. With no less success did he attempt to introduce peace and prosperity into the district of Malwah, of which he had been appointed governor. In 1821 Sir John Malcolm returned once more to England; but on being appointed in 1827 governor of Bombay, he repaired again to India. The influence of this new office was directed to the promotion of cotton and silk cultivation, and to the establishment of steam communication with England. He left India for the last time in 1830; and shortly after his arrival in England became M.P. for Launceston. He died of paralysis in May 1833. Besides the work mentioned above, Sir John Malcolm wrote,—*Sketch of the Political History of India since the Introduction of Mr Pitt's Bill in* 1784 *to the present date*, 8vo, London, 1811; *Sketch of the Sikhs*, 8vo, 1812; *Observations on the Disturbances in the Madras Army*, 8vo, 1812; *Persia, a Poem*, 8vo, 1814; and a posthumous work, *Life of Lord Clive*, 1836. *The Life and Correspondence of Major-General Sir John Malcolm, G.C.B.*, was published by John W. Kaye, 2 vols. 8vo, London, 1856.

MALCZEWSKI, Antoni, an eminent Polish poet, was born about 1792 in Volhynia. At the age of nineteen he entered the Polish army, and was afterwards in the suite of the Emperor Alexander I. until 1816, when, owing to a duel which he had fought, he was forced to quit the service. After travelling for the next five years in Switzerland, Italy, and France, he settled in the Ukraine as a farmer, and devoted his leisure hours to poetry. Compelled, however, by the voice of scandal to leave that district, he removed with a diminished fortune to Moscow. He died there in great poverty in 1826. Malczewski's principal poem, *Maria, a Tale of the Ukraine*, was published at Warsaw shortly before his death. It was printed in the original in London in 1836.

MALDA, a town of Hindustan, in the lieutenant-governorship of Bengal, situate on a river which communicates with the Ganges. The manufactures which were formerly carried on in this town have disappeared before the superior cheapness of those brought from the United Kingdom, and the place has in consequence greatly deteriorated. The district to which this place gives its name is bounded on the N. by Purneah, on the E. by Dinajepore, on the S. by Rajeshahye, and on the W. by Moorshedabad. It has an area of 1000 square miles, and a population of upwards of 400,000. The town of Malda is in E. Long. 88. 11., N. Lat. 25. 3.

MALDIVE, or MALEDIVA ISLANDS, a remarkable group of islands in the Indian Ocean, extending almost in a straight line between Lat. 7. 6. N. and 0. 40. S., Long. 72 48. and 73. 48. E.; 466 geographical miles in length, and 46 or 48 miles in breadth. These islands lie in circular groups or *atolls*, formed by coral reefs, and divided from each other by channels of great depth. The water inside the atolls is generally shallow and calm, though on the surrounding reefs the waves beat with considerable violence. The reefs are not unbroken, and there are many openings which permit the entrance of ships; while the depth within is in most cases sufficient to allow them to cross from one part to another. Four safe channels through the Maldives have been explored by European vessels, and there are other two which are believed to be safe, but which have not as yet been explored. The number of the atolls is 17, and the islands, which are situate for the most part on the coral reefs, are reckoned by the natives to be 12,000 in number, but are believed to amount in reality to three or four times as many. The name is believed to be derived from two words in the Malabar language signifying a thousand islands, from their great number. The atolls are generally circular or oval in their shape, and their circumference is on an average 90 miles. The largest island is Mali, N. Lat. 4. 10., E. Long. 73. 40. It is about 7 miles in circumference, and has a population of about 1500 or 2000. The islands are all of a circular form, and are characterized by a lagoon or lake in the centre, which is found even in the smallest of them.

The soil is sandy, mixed with vegetable remains; and at the depth of about 3 feet a layer of sandstone occurs. All the islands of any size are richly clothed with palms, fig trees, bread-fruit trees, &c., and they are all covered with a thick jungle. On some of them there are plantations of Indian corn and sugar-canes, and a small quantity of cotton is grown, together with millet; but as the soil is not adapted to the growth of rice and wheat, these grains are imported. The food of the inhabitants consists chiefly of fish and cocoa-nuts. A small number of cattle are kept on some of the islands of the largest atolls; but there are no sheep or goats. Notwithstanding their tropical situation, the climate of these islands is not remarkable for great heat; the nights are cool, and the plentiful dews prevent the temperature from exceeding a moderate degree of heat. The inhabitants have attained to some degree of civilization, and carry on a considerable amount of commerce among themselves and with the mainland of India. The different islands have each a peculiar trade of their own, and the communication is kept up by means of boats. The commerce with India is also carried on chiefly by native boats, for though Indian vessels used formerly to frequent these islands, the navigation was found to be so difficult and dangerous, that this practice has been discontinued. The principal articles of export are cocoa-nuts and cowries, together with quantities of salt fish; while grain, cotton, silk, tobacco, and various other European goods are imported. The inhabitants are quiet and inoffensive, and little accustomed to war. They are strict Mussulmans; but, contrary to the usual practice in such countries, the women are not kept in seclusion. The people are governed by a monarch, who is styled Sultan of the Thirteen Atolls and Twelve Thousand Isles, but who acknowledges his dependence on the British government of Ceylon, to which he annually sends tribute. Pop. of the whole group, from 150,000 to 200,000.

MALDON, a municipal and parliamentary borough and market-town, county of Essex, on the right bank of the Chelmer, about a mile from its junction with the Blackwater, 37 miles N.E. by E. of London by road, and 44 miles by the Eastern Counties Railway. It consists of two principal streets, crossing each other at right angles, the largest of which runs from E. to W., and is upwards of a mile in length. The town is only partially paved, but is well lighted with gas, and excellently supplied with water. The buildings are mostly of ancient date, but many handsome structures may be seen of recent erection. Among the public buildings the chief is All Saints Church, a very ancient edifice. There is also an ancient town-hall, supposed to have been built in the time of Henry VI. The town possesses also a free grammar school with a library, which was founded by Alderman Breeder in 1608, besides minor educational and several charitable institutions. The harbour, which is formed by the River Blackwater, is accessible to vessels of 200 tons burden, while those of a larger size are loaded by means of lighters in the offing. The town drives a thriving trade in salt, coal, iron, corn, &c. There is also a good deal of fishing, and fine oysters are got in great abundance here. There are in the town malt-houses, breweries, boat-building yards, sail-lofts, cooperages, soap-works, and iron foundries. The market-day is Thursday; and fairs are held twice a year, in May and September. The borough is governed by four aldermen and twelve councillors, and sends two members to Parliament. This town is supposed to be the ancient *Camulodunum*, from which its modern name seems to have been derived. It was the earliest colony established by the Romans in Britain, and had formerly been the seat of some native princes. Pop. (1851) 5888.

MALDONADO, a seaport-town of Uruguay, South America, on the N.E. shore of the estuary of the Rio de la Plata, 72 miles E. of Monte Video, S. Lat. 34. 53. 30., W. Long. 54. 57. 48. The town is situate about 2 miles from the sea, on an elevation rising to the height of 250 feet, and consists chiefly of brick houses thatched with straw. There is a large square in the centre, occupied by the principal buildings, among which is a new church. A considerable amount of trade in cattle and hides is carried on here; and the harbour, which is separated from the town by a ridge of sandy hillocks, is protected by the island of Gorriti. The surrounding country is an open plain, slightly undulating, and affording excellent pasturage for horses and cattle. Pop. about 1500.

MALEBRANCHE, NICOLAS, a distinguished philosopher of France, was the son of Nicolas Malebranche, secretary to the French king, and Catherine de Lauzon, sister to the viceroy of Canada, and was born at Paris on the 6th August 1638. Of an extremely feeble constitution and deformed habit of body, he received his elementary education from a domestic tutor, and only left the parental roof when sufficiently advanced to enter upon a course of philosophy at the college of La Marche, and subsequently to study theology at the Sorbonne. He resolved to enter the church; and his retiring and studious disposition having

Malesherbes.

induced him to decline the offer of a canonicate in Notre Dame, he, in 1660, entered the famous Congregation of the Oratoire. Up to the age of twenty-six, Malebranche applied himself painfully to the study of ecclesiastical history and biblical criticism; but as he had no taste for such investigations, his efforts met with little success. Having accidentally fallen upon the *Traitê de l'Homme* of Descartes, Malebranche became alive to his true vocation. He was so overpowered by the novelty and luminousness of the ideas, and by the solidity and coherence of the principles of that admirable work, that he was repeatedly compelled, from violent palpitations of the heart, to desist from reading it. Malebranche was from that hour consecrated to philosophy; and after ten years' profound study of the works of Descartes, he produced his celebrated *Recherche de la Vérité*. This work has for its object an inquiry into the faculties of the human understanding, thereby to determine articulate rules for the avoidance of error and the advancement of truth. It contains the germs of all the metaphysical theories developed in Malebranche's subsequent publications, and especially in his *Metaphysical and Christian Meditations*, and his *Discourses on Metaphysics and Religion*. All his works are characterized by originality of conception, elevation of doctrine, and beauty of style; and on their first appearance they met with an extraordinary degree of success. As a writer, Malebranche is placed by the ablest critics side by side with Fénélon; and, singular to say, while vehemently declaiming against the imagination and the study of poetry, there is no writer who has employed that noble faculty with such charming success in giving a grandeur and a glow to the subtlest metaphysical disquisitions, and in lending an attractiveness to the coldest abstractions of the reason. His dialogue between the creature and the Creator, in his *Meditations*, reaches the highest pitch of eloquence and inspiration. Malebranche was less successful in polemics than in pure speculation and in the free expression of his doctrines. He liked better to dogmatize than to discuss; yet after the publication of the *Recherche de la Vérité*, he was dragged, in spite of himself, into a perfect whirlpool of polemics. Like the majority of the great philosophers of the seventeenth century, Malebranche was a mathematician and a natural philosopher; and he was in 1699 chosen an honorary member of the Academy of Sciences. His society was universally courted, and few foreigners of any pretensions to learning neglected, when in Paris, to visit the eloquent philosopher, who had, by his hypothesis of *seeing all things in God*, offered such an ingenious solution of the harassing problem of external perception. His health, never robust, became daily weaker, until he was at last reduced to a skeleton. He died on the 13th of October 1715, "a tranquil spectator," says Fontenelle, "of this long death." (For a full and detailed critical exposition of the philosophy of Malebranche, see the First *Preliminary Dissertation* to the present work, p. 74, *et seq.*)

The following is a list of Malebranche's works:—*Recherche de la Vérité*, 12mo, Paris, 1674. Six successive editions of this work received the author's corrections and additions, and it was translated into Latin, English, and modern Greek. *Conversations Métaphysiques et Chrétiennes*, 12mo, Paris, 1677; *Traité de la Nature et de la Grace*, Amst., 12mo, 1680; *Meditations Métaphysiques et Chrétiennes*, 12mo, Cologne, 1683; *Traité de Morale*, 12mo, 1684; *Entretiens sur la Metaphysique et sur la Religion*, 12mo, 1688; *Traité sur l'Amour de Dieu*, 12mo, 1697; *Entretiens d'un Philosophe Chrétien et d'un Philosophe Chinois*, 1708; *Réponses de Malebranche à Arnauld*, 4 vols. 12mo, 1709; *Rèflexions sur la Prémotion Physique*, 12mo, 1715. (See *L'Eloge de Malebranche*, by Fontenelle; *Dictionnaire des Sciences Philosophiques*; and the *Biographie Universelle*.)

MALESHERBES, Chretien Guillaume de Lamoignon de, minister and last counsel to Louis XVI., was born at Paris on the 6th of December 1721. He was descended of an illustrious family, which had occupied the highest offices in the magistracy, being son of the chancellor of France, William de Lamoignon, and grandson of the celebrated advocate-general Lamoignon. His early education he received at the Jesuits' College, and afterwards applied himself with great assiduity to the study of law, history, and political economy. He was chosen a counsellor of the parliament of Paris at the age of twenty-four, and succeeded his father as president of the Court of Aids in the year 1750, and received the superintendence of the press, which, in his hands, became the means of promoting liberty to a degree beyond all former example in that country. Through his favour, the *Encyclopédie*, the works of Rousseau, and many other free speculations, issued from the press, in defiance of the terrific anathemas of the Sorbonne. The superintendence of the press having been taken from him, and conferred upon Maupeou, he was only the more intent on fulfilling the duties of his presidentship, and opposing arbitrary power. Having presented a remonstrance to the king, containing a free protest against the enormous abuses of *lettres de cachet*, he was banished to his country seat by a *lettre de cachet*, and the Duc de Richelieu, at the head of an armed force, abolished the tribunal. On the accession of Louis XVI. to the throne in 1774, he was chosen minister of state. In this elevated station he was only ambitious to extend the sphere of his usefulness. His first care was to restore to liberty the innocent victims of the former reign, and to encourage commerce and agriculture—endeavours in which he was supported by Turgot, comptroller-general of the revenue. He resigned his office in the month of May 1776. He then set out upon a journey through France, Switzerland, and Holland, and after an absence of some years, he returned to his favourite mansion, fraught with such a stock of valuable knowledge as his age and experience qualified him to appreciate. When, by a decree of the National Convention, Louis was to be tried for his life, Malesherbes, nobly forgetting the manner in which he had been banished from his councils, generously offered to plead his cause. He was the person who announced to the unfortunate monarch his cruel fate, and one of the last who took leave of him when taken out to suffer. In the first days of December 1793, three members of a revolutionary committee of Paris came to his country seat to arrest his eldest daughter and his son-in-law M. de Rosambo, and next day new emissaries appeared, and carried him off with his children. The tribunal of blood would scarcely deign to hear him who had been so long the oracle of justice, and by whom so many victims had been saved from death. Malesherbes heard his sentence without emotion, and marched to death with undisturbed serenity. He perished by the guillotine, with his whole family, at the age of seventy-two, on the 22d of April 1794.

Malesherbes.

Grave errors may be laid to the charge of Malesherbes, but all of these had their source in that love of good which in him was as much a passion as a principle. Malesherbes left a number of MSS. which were dispersed by the vandalism of the Revolution, particularly *Observations sur le Méléze, sur le Bois de Sainte Lucie, sur les Pins, sur les Orchis; Mémoire sur les Moyens d'Accélerer les Progrès de l'Economie Rurale en France; Idées d'un Agriculteur, &c.; Mémoire pour Louis XVI.; Observations sur l'Histoire Naturelle de Buffon et Daubenton; Mémoires sur la Librairie et la Liberté de la Presse; Introduction à la Botanique;* three letters in the *Journal des Savants* on the geological phenomena of the environs of Malesherbes. Under the title of *Œuvres Choisies* have been printed (Paris, 1809) extracts from his most celebrated remonstrances; and we have also *Pensées et*

Maximes de M. de Malesherbes suivies de Réflexions sur les Lettres de Cachet, 1802, in 12mo.

MALHERBE, François de, a celebrated French poet, descended of a noble and ancient family, was born at Caen in 1555. He completed his studies at Heidelberg and Basle; and having quitted Normandy at the age of seventeen, he went into Provence, where he attached himself to the family of Henri d'Angoulême, the natural son of Henri II., and was in the service of that prince till he was killed by Altoviti in 1586. After having served in the wars of the League he returned to Paris, and wrote an ode on the arrival of Marie de' Medici, which established his poetical reputation. At length, Cardinal du Perron being informed of his merit and abilities, introduced him to Henri IV., who took him into his service. After the death of that monarch, his widow, Marie de' Medici, settled a pension of 500 crowns upon our poet, who died at Paris in 1628. Malherbe so far excelled all the French poets who preceded him, that Boileau considers him as the father of French poetry. He had a delicate ear, a very refined taste, and was singularly scrupulous in the choice of his expressions. His poetry is remarkable for graceful and elegant versification, but is deficient in reach of thought and power of imagination. (See *Œuvres de Malherbe*, 1 vol. 4to, Paris, 1797; also *Vie de Malherbe*, by Racan.)

MALLET, David, the author of the ballad of *William and Margaret*, was the son of a small innkeeper at Crieff, in Perthshire, and was born about the year 1700. His real name was Malloch, and he is supposed to have been a descendant of the proscribed clan of Macgregor. According to the most recent account, he studied first at Aberdeen, and afterwards at Edinburgh, and while attending the university in the latter city he became tutor to the sons of the Duke of Montrose. Accompanying his pupils to London, and on a tour through the Continent, and coming in contact with persons of the highest rank, Mallet gradually acquired that knowledge of the world, and that refinement of manners, which were, perhaps, the chief stepping-stones to his subsequent eminence. He fixed his residence in London; and in 1724 published, in No. 36 of the *Plain Dealer*, his ballad of *William and Margaret*, the work by which he is now best remembered. The spirit of this piece seems to have been caught from the two old ballads, *William's Ghaist* and *Fair Margaret*, yet there is sufficient originality in its simple feeling and graceful diction to entitle Mallet to be called its author. It was about this time, when he was moving in the society of the chief wits of the day, and was desirous of expunging every trace of his humble origin, and even of his native country, that Mallet assumed the name by which he is now known. In 1728 appeared his *Excursion*, a servile imitation of the style of Thomson, who was then becoming known to the world. His poem on *Verbal Criticism*, published in 1773, was a satire on Bentley, written to please Pope. About this period Frederick Prince of Wales, who was at variance with his father, and was courting popularity by patronizing literary men, appointed Mallet his under-secretary, with a salary of L.200; and in 1740 employed him, conjointly with Thomson, to write *The Masque of Alfred*, in honour of the birthday of the Princess Augusta. This piece Mallet afterwards entirely altered, and produced, without any great success, on the stage of Drury Lane. In 1742 he married his second wife, the daughter of Lord Carlisle's steward, and received L.10,000 as her dowry. Not content with the liberal fortune which he now possessed, Mallet was yet mercenary enough to become the hired tool of any one. He was employed by Lord Bolingbroke, in 1749 to traduce his deceased patron Pope, in a preface to that nobleman's *Patriot King*, and received as his paltry payment the bequest of his lordship's works. With equal servility did he lend himself to government for the purpose of directing the public vengeance against the ill-fated Admiral Byng. The admiral was shot in 1757, and Mallet received a pension. Towards the close of his life Mallet repaired to France for the benefit of his health, but on feeling that his constitution was rapidly giving way, he returned to England, and died soon afterwards, in April 1765. The base character of the man was now revealed in glaring distinctness. It was discovered that a Life of the great Duke of Marlborough, which he had been hired to write by a legacy of L.1000 from the old duchess, and by a pension from the second duke, and which he had professed during his latter years to be composing, was not even begun.

Mallet was an avowed infidel. "As a writer," says Dr Johnson, "he cannot be placed in any high class. There is no species of composition in which he was eminent. His dramas had their day—a short day—and are forgotten; his blank verse seems to my ear the echo of Thomson." Besides the works already mentioned, Mallet wrote *Eurydice*, *Mustapha*, and *Elvira*, tragedies; *Britannia*, a masque; *Amyntor* and *Theodora*, a poem; and a *Life of Bacon*. His *Ballads and Songs, with Notes and Illustrations*, accompanied by a Memoir by Frederick Dinsdale, were published in London, 1857.

Mallet, *Paul-Henri*, an eminent historian, was born at Geneva in 1730, of a family distinguished for the great number of notable men whom it has produced. After completing his education with marked success, he became tutor to the Count of Calenberg, and in 1752 was appointed regius professor of belles-lettres in the university of Copenhagen. The duties devolving on Mallet in this position were discharged with signal ability; but as the French language was not much cultivated in Denmark at that time, the number of his auditors was for the most part very limited. He employed his leisure time in the study of the old Norse language, and brought to light many important historical facts respecting the ancient inhabitants of the north, almost entirely unknown to their descendants of Denmark or the Scandinavian peninsula. The reception which his work met among the learned drew upon the professor the attention of the king, who appointed him instructor in the French language and literature to the young prince, afterwards Christian VII. In 1760 Mallet returned to his native city; and after having filled the chair of history in the college of Geneva for four years with distinguished success, he was chosen a member of the Council of the Two Hundred. Unmistakeable marks of admiration flowed in upon Mallet from persons of rank and distinction; from the landgrave of Hesse-Cassel, from the Czarina of Russia, and from the Earl of Bute, whose son, Lord Mountstewart, Mallet accompanied to Italy, and afterwards to England, where he was presented to the royal family, and was asked by the queen to write a history of the House of Brunswick. On returning to his native country, Mallet resolved to spend the evening of his days in studious retirement and tranquillity, when, in 1792, the revolution of Geneva, in which he warmly espoused the cause of the aristocratic party, deprived him of what moderate fortune his talents had purchased. Owing to the events of the war, the pensions which he had received from the English queen and from the landgrave of Hesse ceased to be forthcoming; but the government of France, on being made aware of the circumstance, granted Mallet an allowance, which he did not live long to enjoy. He died at Geneva, of an attack of paralysis, on the 8th of February 1807.

Mallet was an associate of the Academy of Inscriptions of France, a member of the academies of Upsal, Lyons, and Cassel, and of the Celtic Society. His principal works are,—*Introduction à l'Histoire de Danemark, ou l'on Traité de la Religion, des Mœurs, des Lois, et des Usages des Anciens Danois*, Copenhagen, 1755-56. This work, the most popular of Mallet's in this country, was translated into English and extended by Bishop Percy in 1770, and has recently been republished, with further additions by Blackwell, in Bohn's Antiquarian Library, under the title of *Mallet's Northern Antiquities*. The *Histoire de Danemark*, from A.D. 714 to 1699, Copenhagen, 1758-65-77, 3 vols. 4to; *De la Forme du Gouvernement de Suéde, avec quelques Pièces Originales, contenant les Lois Fondamentales et le Droit Public de ce Royaume*, Copenhagen, 1756, 8vo; *Histoire de la Maison de Hesse*, 1766-85, 4 vols. 8vo; *Histoire de la Maison de Brunswick*, 1767-85, 4 vols. 8vo; *Des Intérêts et des Devoirs d'un Republicain, par un Citoyen de Raguse*, Inverdun, 1770, 8vo; *Histoire de la Maison et des Etats de Mecklenbourg*, Schwerin, 1796, 1 vol. 4to: it only came down to 1503, and was never finished. *Histoire des Suisses ou Helvétiens*, Geneva, 1803, 4 vols. 8vo; *Histoire de la Ligue Hanseatique*, Geneva, 1805, 8vo; *Mémoirs sur la Literature du Nord*, Copenhagen, 1759-60, 6 vols. 8vo. Also a *Traduction du Voyage de* Will. Coxe *en Pologne, Russie, Suède, et Danemark*, Geneva, 1786, 4 vols. 8vo, with the *Voyage en Norvége*. He also published a new and enlarged edition of the *Dictionnaire de la Suisse*, by Tscharner, Geneva, 1788, 3 vols. 8vo. (See *De la Vie et des Ecrits de P. H. Mallet*, by I. C. L. S. Sismondi, Geneva, 1807, 8vo.)

Mallet-Prevost, *Henri*, the eldest brother of the preceding, was a geographer of some note, born at Geneva in 1727, and died at the same place in 1811.

Mallet-Dupan, *Jacques*, kinsman of the former, and a royalist writer of great power and originality during the French revolution, was born at Geneva in 1749. He was one of the conductors of the *Mercure de France*, and edited the *Mercure Britannique*, published in London during his residence in that city in 1798-99. He died at Richmond in 1800. (See *Memoirs and Correspondence of Mallet-Dupan*, by Sayous, 2 vols. 8vo, London, 1852.)

MALLICOLLO, or Manicola, one of the largest of the New Hebrides group of islands in the South Pacific, in S. Lat. 16. 30., and E. Long. 167. 57. It is about 54 miles in length, and from 15 to 21 in breadth, while it rises to a considerable height. A great part of the surface is covered with forests. Mallicollo was discovered by Quiros in 1606, and visited by Cook in 1774. The inhabitants are diminutive, ugly, and in the lowest state of barbarism.

MALLOW, a parliamentary borough and market-town, county of Cork, Ireland, situate on the N. bank of the Blackwater, 19 miles N.N.W. of Cork, and 145 miles S.W. of Dublin. The high road between Cork and Limerick crosses the river here by a bridge of three arches, at the other end of which stands the suburb of Ballydaheen, included in the parliamentary borough. The town consists of one main street nearly parallel with the river, and is well paved, and lighted with gas. The principal buildings are,—a parish church, a Roman Catholic chapel, two Methodist chapels, an Independent meeting-house, an infirmary, court-house, bridewell, workhouse, spa-house, and barrack. To the W. of the town are to be seen the ruins of an old castle; the whole of the surrounding country is rich and fertile, and contains a number of gentlemen's houses. The town has no manufactures of importance, nor is the river navigable; but a considerable retail trade is carried on here, and a great number of visitors are attracted by the mineral spring which formerly enjoyed the reputation of a holy well, and is still highly prized in cases of dyspepsia, &c. (See Cork County.) In the neighbourhood of the city there are several large flour-mills, and in the town itself tanneries and salt-works. The borough sends one member to Parliament; and the population in 1851 was 5436. Registered electors (1853) 243.

MALMEDY, a town of Prussia, province of Lower Rhine, and government of Aix-la-Chapelle, stands 21 miles S.S.W. of the town of that name, on the S. bank of the Warge. It has three churches, one of them very handsome, a school, and a justice-of-peace court. The manufactures consist chiefly of cotton and woollen stuffs, leather, lace, paper, soap, and glue. There are here also mineral springs, little inferior in quality to those of Spa, but not much frequented. Pop. (1849) 4259.

MALMESBURY, William of, an old English historian, descended by his father's side from the Normans, and by his mother's from the Saxons, was born in Somersetshire about 1095 or 1096. At an early age he entered the monastery of Malmesbury, where he subsequently became librarian and precentor. He is also said to have declined the abbotship. From his youth Malmesbury was an enthusiastic devotee of literature. He explored the chief monastic libraries in the kingdom, and with equal ardour perused books of poetry, divinity, biography, and history. His care in correcting his style is seen by the changes in the four several editions of his *De Gestis Regum* that appeared during his lifetime; and no less evident in his writings is his scrupulous regard for historic truth. His numerous and apposite quotations from Latin authors show that he possessed an acquaintance with their works alike wide and intimate. Malmesbury was in high repute in his own day, and was patronized and befriended by Robert Earl of Gloucester, natural son of Henry I. The date of his death is generally fixed at 1143; but the fact that his *Historiæ Novellæ*, published in 1142, was afterwards subjected to a thorough revisal and emendation, evidently from his own hand, seems to indicate that he must have lived considerably longer.

The following is a list of his works;—*De Gestis Regum*; *Historiæ Novellæ*; *De Gestis Pontificum*; *De Vita Aldhelmi*; *De Vita S. Dunstani*; *Vita S. Patricii*; *Miracula S. Benigni*; *Passio S. Indracti*; *De Antiquitate Glastoniensis Ecclesiæ*; *Vita S. Wulstani Episcopi Wigorniensis*; *Chronica*; *Miracula S. Elfgifæ*; *Itinerarium Joannis Abbatis Meldunensis versus Romam*; *Expositio Threnorum Hieremiæ*; *De Miraculis Divæ Mariæ*; *De Serie Evangelistarum*, in verse; *De Miraculis B. Andreæ*; *Abbrevatio Amalarii de Ecclesiasticis Officiis*, and *Epitome Historiæ Aimonis Floriacensis*. Malmesbury's *De Gestis Regum*, *Historiæ Novellæ*, and *De Gestis Pontificum*, were published by Savile in his *Scriptores post Bedam*, 1596 and 1601. The *De Vita Aldhelmi* and the *De Antiquitate Ecclesiæ Glastoniensis* appeared in Gale's *Scriptores XV.*, Oxford, 1691. The former of these works and the *Vita S. Wulstani* are printed in the second volume of Wharton's *Anglia Sacra*. In 1815 was published *The History of the Kings of England, and the Modern History of William Malmesbury*, translated by the Rev. John Sharpe, 4to, London. This translation has been reprinted in Bohn's Antiquarian Library, 1847.

MALMESBURY, a parliamentary borough and market-town of England, county of Wiltshire, situate on a hill near the Avon, which winds almost round it, and is spanned by several bridges, 17½ miles N.N.W. of Bath, and 86 miles W. of London. The town consists of three main streets not very regularly laid out. The houses are for the most part built of stone; and in the market-place stands an ancient octagonal cross, richly ornamented with carved work, supposed to be as early as the reign of Henry VIII. The town was formerly defended by walls and a castle of some strength, and it possessed a very large abbey, covering 45 acres of ground, of which little now remains except the church, an excellent specimen of early English architecture. Besides this, there is the church of St Mary's; and of a third, St Paul's, little more than the tower now remains. There are also places of worship belonging to the Independents, Baptists, and Moravians, two schools, a savings-bank, and a market-house recently erected. A considerable amount of wool manufacture was formerly carried on here, but now the manufactures are unimportant. There is a silk mill; and tanning, brewing, and lace-making are carried on to a small extent. The place, however, is on the decline, and the inhabitants are mainly engaged in agricultural pursuits. Cattle markets are held here monthly, and three great horse and cattle fairs in the year. The market-day is Saturday. The chief importance of Malmesbury is derived from its antiquity and historical interest. According to the ancient chronicles, a monastery was founded here in the seventh century, which, after being twice burnt by the Danes in the ninth and tenth centuries, finally rose to be one of the principal establishments of the kind in the W. of England, and in the reign of Edward III. was raised to the dignity of a mitred abbey. In the time of Stephen the town, which had then been newly fortified, was an object of some contention, and in the civil war of Charles I. it was taken from the royalists by Sir William Waller in 1643, but it was soon recovered, and again taken a short time after. At this time, too, the church received great injury, and was reduced to its present ruined state. This borough has returned members to Parliament since the time of Edward I. Previous to the Reform Act it had two representatives, but the number has now been reduced to one. The town is famous for its connection with several writers of eminence. St Aldhelm, a Saxon writer of the seventh century, and Thomas Hobbes, sometimes called the "Philosopher of Malmesbury," were born here; and William of Malmesbury, one of the best of mediæval historians, was, during the greater part of his life, a monk of the abbey. Pop. (1851) 6998.

MALMÖ, a seaport-town of Sweden, capital of the laen or province of the same name, stands on the E. shore of the Sound, nearly opposite Copenhagen, from which it is 16 miles distant; N. Lat. 55. 40., E. Long. 13. The town, which stands on a level plain, is well laid out with regular and well built streets, and has a fine square in the centre. Malmö was formerly very strongly fortified, being surrounded by walls and ditches, and protected by a castle; but the walls have been demolished, and only the castle now remains, which is used as a prison and barracks. The square is adorned by a handsome avenue of limes and other trees; and the principal buildings in the town are two churches, one of which has a fine interior and a large organ. The harbour, which consists of a roadstead and an artificial inner basin, is only accessible to small vessels. Being, however, the principal commercial town in the fertile province to which it belongs, it carries on an extensive trade, particularly in grain and brandy. The manufactures are considerable, consisting of woollen cloth, starch, gloves, stockings, hats, carpets, tobacco, soap, &c. Steamers ply regularly between this and Copenhagen, accomplishing the distance in two hours. Pop. 10,203. The laen or province of the same name, of which Malmö is the capital, is one of the richest in Sweden, and comprises an area of 1774 square miles. It is bounded by Christianstad on the N. and E., by the Baltic on the S., and by the Sound on the W. The surface is for the most part level, though occasionally diversified with hills. It includes several lakes. The produce of this district consists of corn, potatoes, hemp, hops, tobacco, and fruits; and the horses and cattle reared here are said to be the finest in Sweden. Corn and cattle are the chief articles of export. Pop. of laen (1850) 253,084.

MALO, St, a seaport of France, capital of an arrondissement of the same name in the department of Ille-et-Vilaine, is situated on the island of Aron, which is joined to the land by a narrow causeway called the Sillon, about three-quarters of a mile in length, 45 miles N. by W. of Rennes; Lat. 48. 39. N., Long. 2. 1. W. The harbour is secure, being sheltered from the sea by the island and the Sillon; but the great number of rocks render the approach both difficult and dangerous. To the W. of the town there is a roadstead, which is separated from the harbour by a chain of rocks, and defended by seven forts. The harbour is dry at low water, but has recently been improved by the formation of a large wet dock. The harbour is much frequented: vessels are fitted out here for India and for the whale fisheries, and a good deal of ship-building is carried on. The chief articles of export are the products of the surrounding country, together with straw hats, woollen and linen fabrics; and it imports sugar, indigo, spices, and other Indian and Chinese wares. The town is strongly fortified, the defences being constructed by Vauban. At the entrance of the town from the Sillon there is an ancient castle of an imposing appearance, built of granite, and having a strong tower at each corner. The fortifications rise abruptly from the water's edge, and the whole surface of the island is covered by the town. The houses are lofty and built of stone; and there is a square in the centre, in which stands the cathedral, the Hotel de Ville, and the episcopal palace. Not far from the town is St Servan, which is sometimes considered as a suburb of St Malo. The manufactures of St Malo consist mainly of sail-cloth, cordage, fish-hooks, hosiery, and soap. This town seems to have been founded in the tenth century; but the island on which it stands was the seat of a monastery as early as the sixth century. Before the rise of Brest, this town was the first seaport in France on the ocean; and Cartier, one of its seamen, was the discoverer of Canada. During the wars with Great Britain the privateers of St Malo did so much injury to their enemies, that the town was three times bombarded by the British, in 1693, 1695, and 1758, but always without success. Pop. (1851) 9383.

MALONE, Edmund, the well-known editor of Shakespere, was the son of an Irish judge, and was born at Dublin in 1741. After graduating at Trinity College in his native city, he studied at the Inner Temple, London, and was called to the bar in 1767. Inheriting, however, a competent fortune, he soon exchanged his professional labours for the more congenial pursuits of literature. In 1780 Malone published two supplementary volumes to Stevens' edition of Shakespere; and his own edition of the great dramatist, in 11 volumes 8vo, appeared in 1790. He also, in 1796, defended the fame of Shakespere by exposing the spuriousness of the MSS. attributed to the poet by the Irelands. Malone was one of the executors of Sir Joshua Reynolds, and in 1797 published the works and a memoir of that great painter. He died in 1812. An edition of his Shakespere, which he had greatly improved during the latter part of his life, was published in 21 volumes, in 1821, by his friend Mr James Boswell. His other works are,—*Cursory Observations on the Poems attributed to Thomas Rowley*, 8vo, London, 1782; *The Prose Works of John Dryden, accompanied with a Memoir*, 1800; and *The Works of William Gerald Hamilton, with a Sketch of his Life*.

MALPAS, a market-town of England, Cheshire, situate on an eminence overlooking the Dee, 13 miles S.S.E. from Chester. It has a fine old parish church, a grammar-school, and several charitable institutions. The Marquis of Cholmondeley, whose castle is in the vicinity, takes the title of viscount from this place. Pop. of parish (1851) 5710.

MALPIGHI, Marcello, an eminent physician and anatomist, was born near Bologna in 1628. He studied medicine in that city, and graduated as doctor in 1653. In 1656 he became professor of medicine in the university of Bologna, but was promoted during the same year by Frederick II. of Tuscany to the medical chair at Pisa. There his intercourse with Borelli, the mathematician, tended greatly to convince Malpighi of the propriety of applying experimental researches to the study of medicine. He was soon forced, however, by declining health, to return to his former situation at Bologna; but in 1666 was called to the office of principal professor at Messina. The opposition, however, with which he was assailed by the advocates of the old school of medicine in that city, induced Malpighi to resign his chair after an incumbency of four years. From Bologna he was summoned in 1691 to Rome, to occupy the position of principal physician to Pope Innocent XII. The discharge of his new duties was rendered burdensome by attacks of gout, palpitation, and other diseases, and he died of apoplexy in 1694. Malpighi's discoveries relate chiefly to the structure of the skin and of the secreting glands. He also devoted much attention to the organization of plants and the lower animals. His chief works are,—*Observationes Anatomicæ de Pulmonibus*, Bologna, 1661; *Epistolæ Anatomicæ de Lingua, de Cerebro, de Externo Tactûs Organo, de Omento, de Pinguedine et adiposis Ductibus*, 12mo, Bologna, 1661–65; *De Viscerum Structurâ*, 4to, Bologna, 1666; *Dissertatio Epistolica de Formatione Pulli in Ovo*, 4to, London, 1666–73; *Dissertatio Epistolica de Bombyce*, 4to, London, 1669; and *Epistola de Glandulis Conglobatis*, 4to, London, 1689. His grand work *De Anatome Plantarum* appeared in 1669. A selection of his works, under the title of *Opera Omnia*, was published in 2 vols., London, 1686. His *Opera Posthuma*, edited by P. Regis, professor at Montpellier, was published at London in 1697.

MALT. See BREWING, and DISTILLATION.

MALTA (anciently *Melita*), an island in the Mediterranean, between Sicily and Africa, 52 miles S.S.W. of Cape Passaro in Sicily. Length 17 miles, breadth 9 miles, area 98 square miles; N. Lat. (of Valetta) 35. 53., E. Long. 14. 31. It has been supposed by some that this island corresponds to one or other of those mentioned by Homer in the *Odyssey*, but this is exceedingly doubtful. The earliest historical information we have respecting Malta is, that it was colonized by the Phœnicians, and used by them as a station in their long trading voyages to the pillars of Hercules and the Atlantic. At a later period we find the island mentioned as a Carthaginian colony; and although there are some traces of a connection between Malta and the Sicilian Greeks, the particulars of this are not known, nor is there any reason to believe that it was ever in other hands than those of the Phœnicians and Carthaginians. In the first Punic war, Malta was laid waste by the Romans in the year 257 B.C.; but it does not seem to have surrendered finally to that power till the beginning of the second Punic war, when it was taken by Tiberius Sempronius. It then became a part of the province of Sicily, and was raised to the dignity of a municipium. Under the Roman commonwealth it seems to have been in a flourishing condition. It is now established beyond all reasonable doubt, that this island was the scene of the shipwreck of the Apostle Paul. During the period of the Roman empire little is heard of Malta, but on the partition of the empire it formed part of the eastern portion, until it was conquered by the Vandals in the fifth century. The Romans, however, regained it under Belisarius in 533 A.D., and kept possession of it till it was conquered by the Arabs in 870. The Arabs engaged to a considerable extent in piratical expeditions, by which means they acquired great wealth, and they retained possession of the island till they were dispossessed by Count Roger the Norman in 1090. The government was then put into the hands of the nobles, clergy, and representatives of the people, popularly elected. The fortunes of Malta were now united to those of Sicily, which belonged to the Normans from 1090 to 1189, to the German emperors from 1189 to 1258, to France from 1258 to 1282, and to the House of Aragon from 1282 till the time of Charles V., who inherited it as King of Aragon. That monarch, in order to secure the island, which was now chiefly important as a military station, without the expense of maintaining a garrison, made a grant of Malta and Gozo, along with Tripoli, to the Knights of St John, who had shortly before been expelled by the Saracens from their former station at Rhodes. When once firmly established here, it was not long before the knights were able to render good service by frequent expeditions against the pirates from Africa which then infested the Mediterranean. This, however, did not fail to draw upon them the vengeance of the Turks, who made an unsuccessful attempt on Malta. This taught the knights the necessity of securing their position, and they accordingly constructed the extensive and strong defences which still remain. The prizes taken by the cruisers in the expeditions against pirates supplied in a great measure the funds required, and the fortifications were constructed by the joint labour of knights, citizens, and peasants. In the year 1565, while La Valette was grand master, Solyman sent against Malta a fleet of 159 vessels. with 30,000 troops, besides a great number of other ships with provisions, ammunition, &c. The whole number that could be opposed to these was 700 knights and 8500 Maltese soldiers. The attack on the castle of St Elmo, which was defended by 300 knights and 1300 Maltese, commenced on the 24th of May. The besieged defended themselves with great courage and vigour, their most formidable weapons being large hoops covered with inflammable materials, which were set on fire, and then hurled blazing from the walls among the assailants. In the first attack the Turks lost 3000 men, and the Christians only 20 knights and 100 Maltese; but the losses of the besieged were supplied by La Valette with others from the burgh and St Angelo, as long as the communication was left open. At length the furious and incessant cannonade of the Turks had levelled the walls of the castle to the rock on which they stood. On this a general assault was again made with the utmost fury; but it was withstood by the knights with equal courage and determination, and although the loss of the knights was great, they were again strengthened by reinforcements the next day. The Turks now completely isolated the castle by drawing an intrenchment between it and the other forts, and soon afterwards renewed the attack. The defence was now desperate, and a fearful contest ensued, which was only terminated by the approach of night; and after La Valette had in vain attempted to send assistance, the knights determined to die at their posts, and during the night they received the sacrament. The next day saw the end of this heroic defence: no quarter was asked or given; the knights all perished at their posts, and the Turks entered the desolated fortress over the dead bodies of its defenders. Notwithstanding the urgent necessity and the repeated request of the grand master, no assistance was sent from Sicily; yet no thought of surrender was for a moment entertained. The siege of the remaining forts was still carried on, and in order to prevent the approach of the Turkish vessels, the Maltese erected stockades, and where the water was too deep, placed booms across the harbour. The Turks sent swimmers with hatchets to cut away these obstructions; but they were met and discomfited by Maltese sailors, who swam from the forts, until, perceiving that no advantage was gained by such contests, the assailants at length desisted from this mode of warfare. The besiegers being now reinforced by a body of Algerians, under the command of the son of Barbarossa, made an attack on the forts with 4000 men, who, though they succeeded in planting their standards for a moment on the battlements, were hurled back by the knights, and all their entreaties for mercy being answered by shouts of "St Elmo," they were massacred till only 500 remained, most of whom were desperately wounded. The assaults, however, still continued, and although always unsuccessful, the numbers of the brave defenders were gradually but surely diminishing. On one occasion, when the Turks deceived their adversaries by a false attack, even the women and children shared in the defence, bringing food to the knights, and stones to repair the walls. But in spite of all, the Turks were on the very point of victory when a sally from a different part of the defences caused a panic among the assailants by the apprehension that the Sicilians had come to the rescue. Till the end of August the attacks were carried on with the utmost fury, and repulsed with incredible courage; but when preparations were being made for the final attempt, the long-expected aid at last arrived, and the Turks not daring to abide more than one encounter with the Sicilians, raised the siege, and took refuge in their ships. During the siege the Christians lost 260 knights and more than 7000 soldiers, and the Turks 25,000. After the departure of the enemy, the handful of knights who remained commenced to rebuild their city, in which they were aided by pecuniary contributions from most of the sovereigns of Europe, and from the distant knights of the Order. The new city was begun in 1566 and finished in 1571, and was called La Valetta, after the brave defender of the island—a name which it still bears. After this time the knights distinguished themselves greatly in the battle of Lepanto in 1571. They also employed themselves in defending the coasts of the Mediterranean; and although the Turks once again (in 1601) threatened Malta, they were immediately repulsed. The knights still preserved in their original strictness the rules of the Order, and strengthened the island by new fortifications, besides building an aqueduct for supplying Valetta with water, and a lazaretto for the sufferers from the plague, which visited Malta in 1669. Great assistance was rendered by the knights of Malta to the European states against the Turks and Africans, in protecting and securing the commerce of the Mediterranean. The earthquake in Calabria and Sicily, in 1783, gave them one of the last opportunities for displaying that chivalrous humanity and beneficence which were the ancient characteristics of their Order. They set out in their ships by night, and did great service to the wretched sufferers at Messina and Reggio. But the French revolution came on, and proclaimed in word and deed that the age of chivalry was gone. The property of the Order in France, Spain, and Italy was confiscated; and finally, in 1798, the island surrendered to the fleet of Bonaparte on its way to Egypt. A garrison of 4000 men was left by the French to defend Malta; but after the battle of the Nile the inhabitants rose against the French, who were besieged in the city of Valetta. A small body of British troops subsequently arrived to the aid of the Maltese, and the French surrendered after a blockade of two years. Provision was made in the treaty of Amiens that Malta should be restored to the knights, on condition that the Maltese should be admitted to the Order; but this was strongly opposed by the Maltese themselves, and the island remained in the possession of Britain till it was finally secured to her at the general peace. Since then, Malta, with the adjoining island of Gozo, has been a part of the British empire.

The coast of Malta is steep and rocky, especially on the S.W., where there is no harbour between Marsa Scirocco on the S.E, and Antifaga on the W. On the W. coast there is the harbour of Magiarro; but on the N.E. coast are the harbours of St Paul, St George, St Julian, and the two harbours of Valetta, which are the largest in the island, and are separated from each other by a projecting tongue of land, on which the city is built; that to the N.W. is called Marsa Musceit, in which there is a small island, used as a quarantine station; while the other, lying to the S.E., is called the Great Harbour. The surface of the island for the most part slopes from the S.W. to the N.E.; and there is a ridge of hills running across the island to the N.W. of Valetta, known by the name of Bengemma, from which numerous smaller ridges run off in various directions. Mount Bengemma, which is the highest point in Malta, reaches the height of 590 feet above the sea. On the western side the cliffs rise perpendicularly from the sea to a height of 300 or 400 feet, while on the E. the coast gradually slopes down to the water's edge. The central ridge divides the island into two parts, in the more easterly of which all the towns are situate; and besides being strong by nature, this barrier has been additionally secured by an intrenchment, known by the name of the Nasciaro Lines. There are neither rivers nor lakes in Malta, and the only places where any swamps occur are St Paul's Bay and the Great Harbour at Valetta, where the sea has retired and left a marshy tract of ground, from which unhealthy vapours are believed to arise. The geological character of the island is chiefly calcareous: there are strata of limestone of various kinds lying on calcareous freestone, and beneath the latter is found a layer of marl. Many petrified animal remains and an abundance of sharks' teeth are to be found here. The rocks of Malta belong to the tertiary formation, and to the older or newer pliocene. The rock is covered in most parts by sand and a rich red clay; but here and there the bare rock projects through the soil; and the country has in general a very dry and barren appearance, except after it has been refreshed by a fall of rain. The vegetation is scanty, and very few trees are to be seen. There are two kinds of stone found here, which are much used for building purposes,—the one is hard and the other soft, though there are many intermediate kinds. The hardest is a coarse sort of marble, remarkable for strength. The other is a soft kind of calcareous sandstone, which is found in much greater quantities, and is used for the ordinary purposes of building. It is very light, absorbent, and easily cut, but when exposed to the air it is apt to crumble away. Alabaster is found in considerable abundance in Malta, but especially in Gozo. In the steep cliffs on the sea-coast there are a great number of remarkable caves and grottos, some of them very large. Many of them are situate at the level of the sea, so that the waves dash in with great noise, while others are higher up the rocks. One of the largest of these is near the promontory called Benghisa, to the W. of the Marsa Scirocco Bay, and extends more than 200 paces into the rock. The soil of Malta is, like its rocks, calcareous, and owes much of its fertility to the porous character of the soft sandstone, which is broken up by the natives, and mixed with soil. Where the rock is too hard for this, they bring soil from other lands, and form it into terraces, using the large stones to form walls, in order to prevent the soil from being washed away. The soil, however, is very fertile, frequently yielding two crops a-year, and never requiring to lie fallow. Cotton is the principal produce of the Maltese islands. Corn is grown in sufficient quantities to supply the inhabitants. Vines are cultivated, but the wine is of inferior quality; figs and oranges are very abundant, the latter especially being of excellent quality. Of animals found in the island, the Maltese dog and hawk were formerly much sought after, but the former of these species is now believed to be extinct. Many of the domestic animals in this island are remarkable for their breed, especially mules and asses. Snakes are found in Malta, but they are harmless,—a fact which the inhabitants ascribe to the miraculous influence of the apostle Paul. The bees are famous for the excellence of their honey, and some have supposed that the island was on this account called *Melite* by the Greeks. Fish is got here in great abundance, and many of the kinds are excellent, especially the dory, rock cod, and a species of whiting called *lupo*. A remarkable shell-fish, called the *Pholas dactylus*, is found at Malta, which bores for itself a hole in the soft rock, so as to give to many parts of the shore a very remarkable appearance.

The climate of Malta is very warm, and in summer the heat becomes oppressive. The greatest heat is between 80° and 90°, while the thermometer never falls below 46°. The radiation of the sun's rays from the rocks tends to increase the heat, and the stones and walls get sometimes so heated during the long days as to retain a high temperature during the night, and render the nights in summer excessively hot and oppressive. The winter at Malta, which extends from October to May, is very pleasant and salubrious. There are no regular land and sea breezes, owing probably to the fact that the temperature of the land remains so high during the night. The most frequent winds are those which flow from the S.E. and N.W.; but the former, the siroccos, are very hot and unhealthy, and generally prevail between August and October. Sudden gusts of heated air occasionally blow across from the coast of Africa, which would be exceedingly dangerous and destructive were they not very limited in duration, in most cases not exceeding half a minute. Snow is unknown in Malta, but hail frequently falls during the winter months. Between the months of December and February rain falls frequently, and often in violent storms; in March the weather is more dry and settled. In April and May the island is refreshed by occasional showers; while during the summer there is not a cloud to darken the clear sky, or mitigate the fierceness of the sun's rays. September and October are the most agreeable months; the temperature is then cool, and the air calm and bracing. This period is called by the Maltese the little summer, or St Martin's summer. Thunder-storms are not frequent, and occur chiefly in spring. The sky is generally clear, sometimes so much so that the summit of Etna, at a distance of 128 miles, is distinctly seen.

The capital of the island is Valetta, situate between the two harbours of Marsa Musceit and the Great Port, on the E. coast of the island. The promontory on which it stands, which was anciently called Mount Sceberras, is nearly 2 miles long, and about three-quarters of a mile broad, and forms a sort of ridge, like the back of an animal, sloping down to the sea on either side, and at the further extremity. At its point stands the fort of St Elmo, with one of the best lighthouses in the Mediterranean. The principal streets run along the ridge, and others, shorter, branch off at right angles; while a carriage drive runs round the whole city between the houses and the fortifications. The ground on which the city is built is so steep that the principal streets in Valetta consist of flights of stairs; but this contributes greatly to facilitate the cleaning of the thoroughfares. The houses are built of stone, with flat roofs, after the eastern fashion. Wood is little used in the houses of Valetta. The streets are well lighted, and paved with the hard stones of the island and lava from Mount Etna. Water is supplied by the aqueduct built by the knights; but every house has a tank for collecting the rain water, and there are numerous wells. The fortifications are exceedingly strong, and almost impregnable; so that at the last siege it could only be reduced by famine. The land side of the town is defended by five lines of fortifications, mounted with 1000 pieces of ordnance; and it is calculated that it would require 25,000 soldiers to man the entire defences in their whole extent. Of the public buildings of Valetta, one of the most remarkable is the cathedral or collegiate church of St John, which contains the tombs of some of the grand masters, as well as the chapels of the knights of the different nations. The pavement of this church is inlaid in marble with the arms of the grand masters; and there is a remarkable silver railing, which owes its preservation, during the French possession of Malta, to its having been disguised by paint. The church is also remarkable for a series of paintings representing the chief events in the life of St John the Baptist, one of which is by Caravaggio, but is not in good preservation. Another remarkable building is the church of San Pubblio, which contains under it a large catacomb, in which are to be seen many skeletons and bones of the ancient friars. Besides these, the other public buildings are,—the palace, which contains several fine pictures and an armoury; the lodges or *auberges* of the knights; the government library; the university, treasury, palace of justice, &c.; all of which, and especially the library and the lodges of Castile and Provence, are well built, and distinguished by great taste and simplicity in architecture. The library consists of about 100,000 volumes; and adjoining it there is a museum, which contains many remains of antiquity. The harbours of Valetta are very good. That called Marsa Musceit is now used as a quarantine harbour. The Great Harbour is very much frequented, and is so strongly fortified that no ship could force a passage in past the batteries which stand on each side of the entrance. A large dry dock has recently been added at an expense of L.100,000, which is capable of receiving the largest ships and steamers.

The only other town of importance in the island is Città Vecchia, or Città Notabile, anciently called *Medina*, which was formerly the capital, and stands near the centre of the island about 6 miles W. of Valetta, on a high ground overlooking nearly the whole of the island. It is the seat of a bishop, and contains a handsome modern cathedral; but the chief interest of the place is derived from the catacombs, which are of considerable extent, about 15 feet below the surface. There are some remarkable ancient remains at a place called Casal Crendi, near the S. coast, but little or nothing is known of their origin. The island of Gozo is situate about 4 miles to the N.W. of Malta. Its form is oval, its greatest length is 10 miles, greatest breadth 5 miles; area 16 square miles. It was originally called *Gaulos* by the Greeks, and *Gaulum* by the Romans; but the Arabs corrupted this name to *Gaudese*, from which has come its modern appellation. The coasts, especially to the S., are steep and rugged. The geological structure of the island is the same as that of Malta, but the soil is better and it is more highly cultivated. The surface is undulating, with several conical hills, apparently of a volcanic nature. In the N.W. some of the hills attain a considerable elevation. Gozo contains no town, but the inhabitants dwell in six small villages. There are two principal forts,—Rabato in the centre, and Chambray in the S., near to the latter of which is the best landing-place and anchorage. Sailing and rowing boats ply daily between Valetta and Gozo, the passage being only 8 miles in length. Between the two larger islands lies Comino, abounding in rabbits, and several other islets and rocks, all of which belong to Malta and Gozo.

The Maltese are of middle stature, strong, and dark in complexion, and the women are remarkable for their oriental style of beauty. The character of the country people resembles that of the Spanish; but in the towns a union of the qualities of the French and Greek nations may be observed. The men are active and industrious, being chiefly employed in agriculture and stone-cutting. They also make the best sailors of any in the Mediterranean. The dress of the lower orders consists of a loose shirt, above which they wear a jacket adorned with silver or gold buttons, and a long scarf wound round their waist. They have also short drawers reaching to the knee, and shoes somewhat resembling the sandals of the ancients. In winter they wear woollen caps, with hoods falling down behind, and in summer large straw hats. The dress of the women is extremely picturesque, consisting of a cotton under-garment, a blue petticoat, a corset with sleeves, and an upper garment which opens at the side. Their usual head-dress consists of a black silk veil, called *faldetta;* but many of the higher classes, both of men and women, have adopted the English and French fashions of dress. The manners of the Maltese are not refined, but they are in many respects superior in their moral character to the other inhabitants of southern Europe. Drunkenness is almost unknown; and the favourite beverages of all classes are coffee and iced water. Tobacco is smoked to a considerable extent. Music and dancing, along with horse and boat races, are the principal amusements in the island.

The government of Malta is exercised by a governor appointed by the crown, with a salary of L.4800 per annum, along with a council of eighteen members, eight of which are elected by the Maltese. The governor presides in the council, in which he has two votes, and a veto on all its proceedings. This constitution was first established in 1849. The total number of acres under cultivation in the three islands in 1854 was, 45,182, of which 7545 were wheat, 6753 meschiato, and 7873 cotton. The quantity of uncultivated ground was 14,274 acres. In the same year there were in the islands 3748 horses, 4396 head of cattle, 9489 sheep, and 3323 goats. The number of ships that entered the port in 1854 was 4783, with a tonnage of 886,790; and of those that cleared in the same year, 4551, with a tonnage of 844,242. There are no returns of the value of the imports and exports of Malta.

The amount of public revenue and expenditure since the year 1850 is as follows:—

Years.	Revenue.	Expenditure.
1850	L.129,293	L.125,362
1851	133,080	119,307
1852	127,729	123,068
1853	123,305	138,034
1854	123,772	141,304

Of the total revenue for 1854, L.76,493 was derived from customs, and L.17,311 from rents, exclusive of land. Of the expenditure in the same year, L.47,927 was employed on the fixed establishment; L.13,744 on pensions, retiring allowances, &c.; L.16,297 on hospitals and charitable allowances; L.694 on education; L.28,429 on public works, buildings, roads, &c.; and L.6200 on military expenses. The number of schools in the islands in 1854 was 32, containing a total of 4969 scholars. The number of births in the year 1854 was 4698; of deaths, 3981; of marriages, 711. Pop. (1854) 131,401.

MALTE-BRUN. See Brun.

MALTHUS, Thomas Robert, was born in 1766, at the Rookery, in the county of Surrey. His father, Daniel Malthus, a gentleman of good family and independent fortune, much occupied in classical and philosophical pursuits, was the friend and correspondent of Rousseau, and ultimately one of his executors. From the age of nine or ten, until the time of his admission at Cambridge, young Malthus remained under private tuition, and was sometimes a solitary pupil in the house of his tutor. He had for his instructors Richard Graves, author of the *Spiritual Quixote*, and Gilbert Wakefield, the editor of Lucretius and other classics, and the correspondent of Mr Fox.

In 1784 young Malthus was removed from Mr Wakefield's house to Jesus College, Cambridge, where he obtained prizes for declamations both in Latin and in English, and on taking his degree in 1788, his name appeared in the *Tripos* as the ninth wrangler. He also found time for the cultivation of history, literature, and poetry; and in 1797 he was made fellow of his college. Having about the same time entered into holy orders, he undertook the cure of a small parish in Surrey, but he occasionally resided in Cambridge on his fellowship, for the purpose of pursuing with more advantage the course of study to which he was attached. In 1798 appeared the first edition of his great work, an *Essay on the Principle of Population as it affects the Future Improvement of Society, with Remarks on the Speculations of Mr Godwin, M. Condorcet, and other writers*, in 1 volume octavo. In this production the general principle of population which Wallace, Hume, and others, had very distinctly enunciated before him, though without foreseeing the consequences which might be deduced from it, was clearly expounded, and some of the important conclusions to which it leads, in regard to the probable improvement of society, were likewise stated and explained; but his proofs and illustrations were still imperfect, and he himself was yet scarcely aware of the whole extent and bearings of the subject. The book, however, was received with some surprise, and excited considerable attention, as an attempt to overturn the theory of political optimism, and to refute, upon philosophical principles, the speculations, then so much in vogue, of Godwin and others, as to the indefinite perfectibility of human institutions. (With respect to Malthus's views, see the articles Colony and Population.) In 1799 Malthus sailed for Hamburg in search of materials for the exposition of his grand principle, along with Dr Ed. Daniel Clarke and others. He visited Sweden, Norway, Finland, and part of Russia, the only countries at that time open to English travellers. Of this tour he has left other memorials besides those embodied in his own work, and amongst these may be mentioned the valuable notes which have since served to enrich the last volume of Dr Clarke's Travels. During the short peace of Amiens, he visited France and Switzerland; exploring all that was most interesting in these countries, and continuing, wherever he went, to collect facts and documents for the illustration of the principle he had announced, and the completion of his work. In 1805 he was appointed professor of modern history and political economy at Haileybury, a situation in which he remained until his death. It has sometimes been insinuated that Malthus was indebted to his father for those new views of population which first appeared in the essay already noticed, and which subsequently attracted so much attention. For this surmise, however, there appears to have been no foundation whatever. That the mind of Mr Malthus was set to work upon the subject of population in consequence of frequent discussions between his father and himself, he has fully admitted; but no two individuals ever entertained opinions more opposite, or differed more completely respecting the very principle which the one is alleged to have suggested to the other.

Exclusive of the *Essay on Population*, the principal productions of Mr Malthus were,—*An Inquiry into the Nature and Progress of Rent*, 1815; *The Principles of Political Economy*, 1820; and *Definitions in Political Economy*, 1827. But none of these made any permanent addition to his fame. The Inquiry in regard to Rent is an ingenious, and probably also an original speculation; but it has since been ascertained that the theory explained by Malthus in his tract, had been discovered and set in a very clear light by Dr Anderson in an Essay on the Corn Laws, published in 1776. The treatise on Political Economy is very ill arranged, and is in no respect either a practical or a scientific exposition of the subject. It is in great part occupied with an examination of parts of Mr Ricardo's peculiar doctrines, and with an inquiry into the nature and causes of value. Nothing, however, can be more unsatisfactory than these discussions. In truth, Mr Malthus never had any clear or accurate perception of Mr Ricardo's theories, or of the principles which determine the value in exchange of different articles. His *Definitions* have all the faults of his *Political Economy*, and never exercised any influence.

The latter years of Mr Malthus's life were passed in the society of his family, in the exercise of his ministerial and official duties at the college, and in the cultivation of the studies more immediately connected with them. Most of the statesmen of his time, and all the eminent political economists, embraced his opinions in regard to population, and, in their several departments, paved the way for that practical application of his principles, in regard to the poor laws, which has since taken place. He was honoured with distinctions from several sovereigns of Europe, and elected a member of the most eminent literary and scientific societies, particularly the National Institute of France and the Royal Academy of Sciences at Berlin. He was one of the founders of the Political Economy Club, and of the Statistical Society. He died at Bath of an affection of the heart, on the 29th of December 1834.

MALTON, NEW, a municipal and parliamentary borough and market-town of England, in the North Riding of Yorkshire, is situate on a hill on the right bank of the River Derwent, which forms the boundary between the North and East Ridings, 18 miles N.E. by N. of York, and 217 N. by W. of London. The town is clean and well built, and the principal streets meet in a central market-place, in which the town-hall stands. There are two ancient churches, one of which exhibits a fine specimen of Norman architecture; and places of worship for Baptists, Methodists, Independents, Wesleyans, and Unitarians. Malton possesses national, British, and infant schools; and there is also a public grammar-school in the suburb of Norton, which stands on the other side of the Derwent, and is joined to Malton by a handsome stone bridge. There are also in the town a theatre, public rooms, a literary institute, a dispensary, and a savings-bank.

The town has several breweries and tanneries, but its prosperity is principally derived from its trade, which is considerable, the river being navigable to a short distance above the town. Agricultural produce, such as flour, corn, bacon, butter, &c., are sent to Hull, Leeds, &c. The market-day is Saturday, and fairs take place three times a-year. The quarter sessions for the North Riding, together with a county court, are also held here. Malton stands on the York and Scarborough Railway, and it returns two members to Parliamant. Pop. (1851) 7661.

Old Malton, which is included in the parliamentary borough, is situate about a mile N.E. of the new town, on the same side of the river. Some Roman remains have been found here, and it is by some believed to occupy the site of the ancient *Camulodunum*. In the year 1150 a priory was founded here, the remains of which, as well as an ancient church, are still to be seen. Shortly afterwards the Norman family of De Vesci, or Vesey, built a castle here, which was demolished by Henry II. The town was afterwards rebuilt in the reign of Stephen. Old Malton contains a Wesleyan chapel and several schools, and is remarkable for its lime quarries, and also for the ancient Roman remains that have been found in the neighbourhood.

MALUS, ETIENNE LOUIS, the discoverer of the laws of the polarization of light by reflection, born at Paris on the 23d of June 1775, was the son of Anne Louis Malus du Mitry, and of Louisa Charlotte Desboves, his wife.

His father had a place in the Treasury of France, and gave him at home an excellent education in mathematics and in the fine arts, as well as in classical literature, with which he rendered himself so familiar as to retain many passages of the *Iliad* in his memory throughout life. At seventeen he was admitted, after a severe examination, as a pupil of the School of Military Engineers; and about the same time he amused himself with writing a regular tragedy in verse on the death of Cato. He soon distinguished himself in his military studies, and he was about to obtain a commission as an officer, when an order of the minister Bouchotte imputed to him the offence of being a suspected person, probably on account of the situation held by his father, and he was dismissed from the school. He was then obliged to enter the army as a private soldier in the fifth battalion of Paris, and he was employed in this capacity upon the fortifications of Dunkirk. Here he was soon distinguished by M. Lepère, the director of the works, as superior to his accidental situation; and he was selected as one of the young men who were to constitute the members of the *Ecole Polytechnique*, then to be established upon the recommendation and under the direction of Monge, who immediately chose him, from a previous knowledge of his merit, as one of the twenty who were to be made instructors of the rest. This body constituted at that moment the only refuge of the sciences in France, and the enthusiasm of its members was proportionate to the advantages which they enjoyed, and to the importance of the trust committed to them. In the three years which he passed in this institution he was much employed, amongst other applications of the higher geometry, in pursuing the mathematical theory of optics, a department of science in which he was afterwards so eminently to distinguish himself by experimental discoveries. He was then, however, obliged to abandon for a time the pursuit of scientific investigations, and he was admitted into the corps of engineers; with the seniority of his former rank in the school. He served in the army of the Sambre and Meuse; he was present at the passage of the Rhine in 1797, and at the affairs of Ukratz and Altenkirch. Whilst he was in Germany, he formed an attachment with Miss Koch, the daughter of the chancellor of the university of Giessen; and he was on the point of marrying her, when he was obliged to join the Egyptian expedition. He was present in that campaign at the battles of Chebreïs and of the Pyramids; he was also present at the affair of Sabish, at the siege of El Arish, and at that of Jaffa. After the surrender of that place, he was employed in the repairs of the fortifications, and in the establishment of military hospitals. Here he was attacked by the plague, and fortunately recovered from it without any medical assistance. He was then sent to fortify Damietta; he was afterwards at the battle of Heliopolis, at the affair of Ceraim, and at the siege of Cairo. After the capitulation with the English, he embarked on board the transport "Castor," and arrived in France on the 26th of October 1801. His health was exhausted, and his spirits were broken by fatigue and anxiety; but his attachment to his betrothed bride was undiminished, and he hastened to Germany to fulfil his engagement. His fidelity was rewarded, during the eleven years that he survived, by the most constant and affectionate attention on the part of his wife; and she died a year or two after him, a victim to the same disease which had been fatal to her husband.

He had, however, enough of strength and vigour of constitution remaining to enable him, besides the official superintendence of the works carrying on at Antwerp and at Strasbourg, to pursue the study of his favourite sciences; and upon occasion of a prize question proposed by the Institute, he undertook the investigation of the extraordinary refraction of Iceland crystal, which the experiments of Dr Wollaston had previously shown to agree very accurately with the laws laid down by Huygens; and besides completely confirming all Dr Wollaston's results, he had the good fortune greatly to extend the Huygenian discovery of the peculiar modification of light produced by the action of such crystals, which Newton had distinguished by the name "Polarity," and which Malus now found to be produced in a variety of circumstances, independently of the action of crystallized bodies. It seems natural to suppose that the investigation of the laws of the internal reflection of light at the second surface of the crystals, must have led him to the discovery of the effects of oblique reflection in other circumstances; but according to Biot, there was more of accident in his actual progress; for he informs us that Malus had been looking through a piece of crystal at the image of the sun, reflected from the windows of the Luxembourg, to the house in the Rue d'Infer, where he lived, and that he was much surprised to find one of the double images disappear in a certain position of the crystal, although the next day, at a different hour, he could no longer observe the phenomenon, from the alteration of the angle of incidence.

The merit of his discovery was soon acknowledged by his election as a member of the Institute, as well as by the adjudication of a biennial medal from the Royal Society of London, on the foundation of Count Rumford. It has been thought creditable to the Royal Society to have conferred this distinction in the time of a war between the two countries; but if any credit were due for only doing justice conscientiously, it would attach, on this occasion, to those members of the council who saw their own optical speculations in great danger from the new mass of evidence which appeared likely to overthrow them, at least in the public opinion, and who were still the most active in offering this tribute of applause to the more fortunate labours of a rival.

Nor was the remuneration of Malus confined to empty honours only; from the liberality of the French government, he obtained promotion in his own profession *as a military man;* and this not for services performed in the field, nor even in a difficult and dangerous expedition to unknown regions, but for experiments made with safety and tranquillity in his own closet. That government had not carried the refined principle of the division of labour so far as to resolve that all public encouragement should be limited to the precise department in which a public service had been performed; and hence a mark of distinction, which a gentleman could accept without degradation, was not deemed an incommensurate remuneration for a discovery in abstract science. Such a refinement, which has been practically introduced into our own country, might appear, to a man who had a heart, something worse than sordid; he might fancy that a great nation, as well as a great individual, should treat its dependents, "not according to their deserts, but after its own honour and dignity." If, however, a person in office happened to have anything like a heart about him, the outcry of an indiscriminating opposition would soon teach him to silence its dictates.

1. M. Malus's first publication appears to have been a paper "On an Unknown Branch of the Nile," in the first volume of the *Décade Egyptienne.* 2. He presented to the Institute a mathematical "Traité d'Optique," before the completion of his experiments on double refraction; it was published in the *Mémoires présentés à l'Institut,* vol. ii., Paris, 1810. 3. His more important discoveries were first made known in the second volume of the *Mémoires d'Arcueil,* Paris, 1809, 8vo; and again, 4, in the "Theory of Double Refraction," *Mém. Près. à l'Inst.,* vol. ii., a paper which obtained a prize on the 2d of January 1810. 5. In a short "Essay on the Measurement of the Refractive Force of Opaque Bodies," contained in the same volume, he employs the method, before made known by Dr Wollaston, for conducting the experiment, and computes the forces concerned upon the Newtonian hypothesis, applied, however, in a manner somewhat arbitrary to the circumstances of the problem. 6. Remarks on some "New Optical Phenomena," *Mèm. Inst. Sc.,* 1810, p. 105, Paris, 1814, read 11th March 1811. This paper is principally intended to prove that two portions of light are always polarized together in opposite directions, and that no part of the light concerned is destroyed, "as Dr Young had been inclined to suspect." The author found that light transmitted obliquely through a number of parallel glasses at a proper angle, becomes at last completely polarized. M. Arago had discovered a case which appeared to be an exception to the general law of the polarization of transmitted light; but it was afterwards readily explained from the theory of the production of colours by interference, as applied to transmitted light. A letter containing the substance of this paper was published in Thomson's *Annals,* iii. 257, April 1814, on occasion of some discoveries of Sir David Brewster, which had been supposed to be wholly new. 7. "On Phenomena accompanying Refraction and Reflection," p. 112, read 27th May, showing the universality of polarization at a proper angle, and examining the effect of a metallic surface. 8. "On the Axis of Refraction of Crystals," p. 142; describing an apparatus for finding the properties of bodies with respect to polarized light, applied to the determination of the axis of crystals, and to the examination of the structure of organized bodies, which appear in general to have certain axes of polarization, as well as those which are manifestly crystallized.

The zeal and energy of Malus supported him to the last, not only in the continuance of these interesting investigations, but also in his duties as an examiner at the *Ecole Polytechnique.* He died on the 24th of February 1812, universally regretted by the lovers of science in all countries, and deeply lamented by his colleagues, who said of him, as Newton did of Cotes, that if his life had been prolonged, we should at last "have known something" of the laws of nature. (For a full account of Malus's discoveries see the Sixth *Preliminary Dissertation,* chap. v., § 2. See also Delambre, *M. Inst.* 1816, p. xxvii.; Biot, in *Biographie Universelle,* xxvi., Paris, 1820.)

MALVERN, GREAT, a watering-place of England, county of Worcestershire, 8 miles S.W. by S. of Worcester, and 119 N.W. by W. of London, occupies a beautiful site on the eastern side of the Malvern Hills. There is an ancient church at Malvern, which formerly belonged to a monastery founded by Edward the Confessor, and was purchased by the inhabitants on the dissolution of the monastery. This church is one of the finest specimens of Gothic architecture in the kingdom. The town is irregularly built, but there are many fine villas and houses in the neighbourhood. It has a chapel of the Countess of Huntingdon's Connection, a handsome library, national and endowed schools, a dispensary, &c. Malvern is chiefly noted as a fashionable watering-place, and it is much frequented on account of its medicinal waters and its general salubrity. Baths and hotels have been built, and gardens and walks laid out, for the accommodation of the visitors. Pop. of parish (1851) 3763.

MALVERN, *Little,* is a village about 3 miles to the S. of the former. The Malvern Hills extend N. and S. for nearly 9 miles, with a breadth of 1 or 2 miles, and separate Worcestershire from Hereford and Monmouth. They rise with a gentle slope, and the three greatest elevations are the North Hill, Worcestershire Beacon, and Herefordshire Beacon, the last of which is 1444 feet above the level of the sea.

MALVOISIN, or MAWMOISINE, WILLIAM DE, some time chancellor of Scotland, was bred in France, and has been thought by some to have been a native of France. Soon after his coming to this country, he was made one of the *clerici regis,* and archdeacon of St Andrews, in which latter capacity we find him present at the christening of the young prince, afterwards King Alexander II. He was constituted chancellor of Scotland on the death of Hugh, Bishop of Glasgow, 6th September 1199, about which time also he was elected into the see of Glasgow, and was consecrated the following year by a special precept from Pope Innocent III. In 1202 he was translated to St Andrews, when he seems to have resigned the chancellorship. In September 1208 he dedicated the new cemetery at the monastery of Dryburgh. (Chalmer's *Caledonia,* ii. 339.) In 1211 we find him, and Walter, Bishop of Glasgow, possessed of legatine powers from Rome, and assembling at Perth a great council of the clergy and people, to press upon them the pope's will and command that an expedition be undertaken to the Holy Land. In 1214 he attended the coronation of King Alexander II., and is said to have set the crown on the head of that monarch. The following year he went with the Bishops of Glasgow and Moray, and Henry, Abbot of Kelso, to the fourth Lateran council, where he remained till 1218; and in the ninth year of King Alexander II. he made a mortification for the soul of King William. He brought into this country from the Continent some Orders of monks and mendicants, till then unknown here, and had convents of Dominican friars erected at Aberdeen, Ayr, Berwick, Edinburgh, Elgin, Inverness, Montrose, Perth, and Stirling, and monasteries for the monks of Valliscaulium at Pluscardine in Moray, Beaulieu in Ross, and Ardchattan in Argyll. He wrote lives of the popish saints Ninian and Kentigern; and it was to him and in his time that Pope Innocent III. sent the decretal letters which appear in the *Corpus Juris Canonici* (*Decret. Greg.*, b. iii., tit. 49, c. 6) to the King of Scots; and (b. iii., tit. 24, c. 9; b. iv., tit. 20, c. 6; and b. v., tit. 39, c. 28) to the Bishop, Archdeacon, and Abbot of St Andrews respectively. The zeal of this bishop for holy church is evident; but it was not his only passion, for on one occasion we find that he deprived the abbey of Dunfermline of the presentation to two churches, because the monks had failed to provide him wine for supper. Fordun says the monks had indeed supplied wine, but the bishop's attendants had drunk it all up. In a composition regarding tithes, anno 1277 (Connel, *Tith.* ii. 413), there is reference to an ordinance, "Willielmi dicti Mawvoisin, Episcopi Sancti Andreæ." Malvoisin continued Bishop of St Andrews till his death, which happened on the 9th of July 1238. (Fordun; Keith's *Bishops;* Chalmers's *Caledonia,* vol. iii., p. 616.)

MALWAH, an extensive province of Hindustan, situate principally between the 22d and 23d degrees of N. Lat. On the N. it is bounded by the provinces of Ajmeer and Agra, on the E. by Allahabad and Gundwaneh, on the S. by Khandesh and Berar, and on the W. by Ajmeer and Gujerat, being in length about 220 miles, and in average breadth 150. Malwah is a central and mountainous region, but with a regular descent from the Vindhya Mountains, which extend along the north side of the Nerbuddah. From these mountains numerous streams descend in every direction, whence they flow N. and S., joining in the former case the Chumbul, and in the latter the Nerbudda. The principal of these are,—the Parbutty, the Chumbul, Betwa, Sinde, Sopra, and Cane; the Mahy, which has its source in the Vindhyan Hills, and also the Nerbuddah, flow in the opposite direction from the abovementioned rivers, and lose themselves in the Gulf of Cambay. The land, notwithstanding its elevation, is extremely fertile, the soil being in general a fine black mould, which produces cotton, opium, sugar, indigo, tobacco, and grain, in large quantities, beside furnishing pasture for numerous herds of cattle. The tobacco, particularly that of the district of Bilsah, is highly esteemed, and carried to all parts of the country. The opium is also much esteemed, and is cultivated to a great extent. Barley is not cultivated, owing to the unfavourable soil; and rice only in a few detached spots, which lie convenient for water. The chief towns are,—Oojain, Indore, Bopal, Bilsah, Seronge, Mundessor, Burseah, and Mundoo. The rivers are not navigable; and being an inland province, the commerce is carried on by means of land carriage. The chief articles of export are cottons, coarse-stained and printed cloths, which are sent in large quantities to Gujerat and to Mirzapoor, on the Ganges, and thence forwarded to Calcutta; the root of the *Morinda citrifolia,* and opium, which last drug is exported to the adjacent provinces, especially to Gujerat and Cattywar, whence it is smuggled eastward. The province of Malwah was rendered tributary to the Patan sovereigns of Delhi in the thirteenth century. During the fourteenth and fifteenth centuries it was governed by independent sovereigns of the Patan or Afghan race. Malwah was subdued, and continued to form a province of the Mogul empire until the death of Aurungzebe in 1707, when it was invaded and overrun by the Mahrattas, and separated from the Mogul dominions, about the year 1732. The ancient land-holders, however, still retained some forts, which they resolutely defended, until their invaders conceded to them a portion of the rents of the neighbouring villages. These people are called Grassias; and one of them retained a mud fort within 10 miles of Oojain in 1790. There were other petty chiefs who held hereditary possession of certain parts of the country, and who possessed each one or more strongholds, which were frequently defended with obstinacy against the rulers of the province. In the southern division of Malwah the Bheels or savage tribe are found in considerable numbers, especially among the mountains contiguous to the Nerbuddah and Taptee rivers. Malwah was the seat of the Pindarrie power, whence they issued in predatory bands to pillage and destroy the country. In 1818, after the war against them had been brought to a successful conclusion, they took refuge in Malwah, their ancient haunt, and still meditated new insurrections. But they were pursued with such activity by the British troops under the orders of Sir John Malcolm, that they were driven to the hills; and being pursued to their fortresses, they were in the end entirely routed and dispersed. The great object of the British in penetrating into these remote parts was to put down entirely the spirit of disorder and rapine by which all ranks appeared to be animated, having been long inured to the most unbounded license, and to restore peace in those regions of Central India which had long been the scene of anarchy. For this purpose, having subdued the leaders of the Patan mercenaries and the Pindarries, Sir John Malcolm distributed his troops in such convenient positions as to awe the disturbers of the public peace into submission, and to preclude all attempts at violence by the disorderly bands who were still lingering in the country, and ready for any violence. By a judicious combination of conciliation with firmness, Sir John Malcolm succeeded in restoring order in the distracted country. The result of his arrangements was the expulsion of the disorderly bands by which the public peace was disturbed, the restoration to power and security of the rulers of the different petty states, and the return to their homes of peaceable and industrious classes, who, during the reign of terror and anarchy, were forced to hide their heads in obscurity. The same talents and statesman-like policy were displayed by Sir John Malcolm in his transactions with the Grassia, Rajpoot, and Bheel freebooters, who were reclaimed from their wild habits, and converted into trustworthy soldiers and industrious cultivators. (E. T.)

MAMERS, a town in the department of Sarthe, in France, capital of an arrondissement of the same name, is situate near the source of the Orne, in a hilly and barren country, 27 miles N.N.E. of Le Mans. The town contains two squares, but the streets are few and unpaved. The principal buildings are,—the government offices, a college, a theatre, and a prison; and there are manufactories of linen, calicoes, hosiery, &c., besides tanneries and breweries. There is also a considerable trade in grain, wine, brandy, wax, cattle, and sheep. The town is supposed to have derived its name from a temple of Mars erected in this district by the Romans; and was anciently a place of considerable strength. After being for some time in the possession of the English, the fortifications were destroyed by them in 1428. Pop. (1851) 5960.

MAMMALIA.

History.

Mammalia (from *Mamma*, breast) is a term in natural history applied to those animals which give suck to their young; and it consequently includes not only all quadrupeds, commonly so called, but also the cetaceous tribes, or whales. The Mammalia form the first class of the Animal Kingdom, and may be defined as follows: They produce their young alive, and nourish them by means of milk; they possess a heart with two ventricles,—lungs,—warm blood,—a voluminous brain, with a corpus callosum,—complete senses,—a muscular diaphragm between the chest and abdomen, and seven cervical vertebræ.[1]

The natural history of quadrupeds certainly forms one of the most interesting and important departments of zoology. The class itself exhibiting a vast range in size and structure, from the delicate harvest mouse to the enormous whale, presents us with so many species of the highest economical value to the human race, that selfishness alone, or at least the desire of immediate personal advantage, would suffice to induce their attentive study, independent of any more philosophical consideration. The study of the organization of quadrupeds has also been of great advantage in throwing a clear and steady light on several points which would otherwise have long continued extremely obscure in the physiology of man. We need scarcely say to any one who has witnessed even their external aspect, that the quadrumanous tribes, or monkeys, are nearly allied in conformation to the human race; and that the lord of the creation, in spite of his spiritual attributes, his intellectual nature, and immortal destiny, holds many things in common with the brutes that perish. He is himself a mammiferous animal, and closely allied, in organization and many physical qualities, to the other orders of his class; nor can it be expected that experience, derived from the practical observation of the other three great classes of the vertebrated animals, to wit, birds, reptiles, and fishes, will ever avail to the physiologist in a way so full and satisfactory as that deduced from the careful study and observance of the mammiferous tribes. At least the latter furnish by far the most immediate and logical affinities to the human race. In regard to the economical uses of quadrupeds, it is scarcely necessary to say, that they supply us with the most truly precious of our earthly gifts. What in themselves are the ingots of pure gold, or the most dazzling lustre of barbaric gems, compared in value with the ample covering of our fleecy flocks? Without the horse, the ox, the sheep, and the dog, how different would be the social, commercial, and political conditions of the most civilized tribes of the human race! Without his rein-deer how would the forlorn Laplander support either his "sleepless summer of long light," or the desolate gloom of a snow-enshrouded winter? Without the enduring camel the desert sands of Africa, if not lifeless solitudes, would at least be nearly impassable to the human race, and as useless for all commercial purposes as an ocean without ships.

History.

It is true, indeed, that every being in nature, the most apparently insignificant production of a Divine Creator, is necessarily deserving of the most studious attention, on the part not only of the philosophical naturalist, but of every intelligent and instructed mind; yet it must be readily admitted, that the creatures with which the great mass of mankind have the most immediate connection, and in the history of which we are most interested, either from the advantages they yield, or the injuries they inflict, are those which may naturally claim our chief attention. Indeed all branches of natural history are in themselves so interesting, independent of any economical result, that each in its turn, when steadily regarded, seems to claim the precedence; and we fear that certain of the treatises on the subject which have already appeared in this work, may have been deemed as somewhat too extended by those who had not previously considered the beauty and excellence of such topics. Indeed we doubt not that many may still regard an insect chiefly as a thing to be trampled on, and a reptile as one to be more carefully avoided; and it probably results from this wide spread persuasion, that even modern authors not seldom commence their entomological or other expositions of the so-called inferior tribes, with something like an *apology* for discussing the attributes of such lowly creatures. To us it seems to be enough to know that they have been created—that they consequently form parts of that magnificent circle of organic life—of those wonders "manifold" which we are desired to magnify, and the least obtrusive of which are well worthy of the most deliberate study by the deepest mind. We scarcely think, then, that an "apology" is necessary between man and man for any degree of devotion to the works of God; and this, so far as concerns the mammiferous tribes with which we are now about to be engaged, will probably, from the undeniable importance of the subject, be at once admitted. Few are so sceptical as to doubt the merits of beef and mutton, and every one may feel kindly disposed towards a study which numbers, in its subject-matter, so many materials that feed, clothe, and enrich the human race.

We do not propose to enter into any lengthened historical exposition of this branch of science from remote periods to the present times. Such investigations may be met with in many accessible works, and would here occupy too much of that space within which we must endeavour to illustrate the more important features of the actual subject. A few brief notices, however, may not be misbestowed on the principal epochs which characterize the investigations of the human mind in this important department.

---

[1] An inconvenient animal the Ai, or *Bradypus tridactylus*, Linn., is the only known quadruped hitherto supposed to present an exception to the character last above named; and it appears from recent investigations, that even this solitary exception is more apparent than real. "An isolated exception to a rule so general, and obtaining in cases of such diversified forms as those to which I have alluded, presents itself to the mind of every one accustomed to look at the general harmony of the established laws of formation, as a violation of that unity of design which constitutes one of the most interesting objects of our investigation, especially as the exception itself is abrupt and sudden, and without any of those intermediate gradations of structure by which the mind is prepared, as it were, for considerable diversities of form, and which so generally soften the transitions which the different offices of the same organ in different groups may render necessary. It was from this consideration rather than as merely correcting a generally received error, that I found, with feelings of no ordinary satisfaction, that in truth this numerical law is not departed from in the present instance, and that the animal in question forms no such exception to the general rule as had been asserted; the two vertebræ which have hitherto been considered as the eighth and ninth cervical, being in fact the first and second dorsal, each of them bearing a pair of rudimentary ribs, moveably articulated to their transverse processes by a true articular surface. This fact I have ascertained by the examination of two skeletons in my possession, one of which is an adult, and is artificially articulated, the other very young, and preserved as a natural skeleton in spirit."—See *Observations on the Neck of the Three-toed Sloth, Bradypus tridactylus*, Linn., by Thomas Bell, F.R.S., in *Transactions of the Zoological Society of London*, vol. i. p. 113.

Although among very ancient authors some valuable distinctive principles were pointed out which remained long unattended to, and have been recognised and acknowledged in their due importance only in comparatively recent times; and although the fact of our thus, with all our additional appliances and stores of knowledge, merely as it were retracing what had been ascertained and recorded by those whose mortal remains have now for so many ages mouldered in the dust, cannot but prove the value of ancient discoveries and observation; yet, upon the whole, it cannot be said that any work of a remote antiquity presents an accurate picture of the truth of nature. Fact and fable are in most instances so intermingled, and a distinct appreciation and lucid description of individual features so frequently blended with unreal or fantastic characteristics, that to derive advantage from such lucubrations, the reader would require to be as learned as his author. At least a constant watchfulness must be kept up, lest the fictions of imagination be received as the records of truth.

Although in Herodotus, the "Father of History," we find a few casual indications regarding quadrupeds, and a greater number in the later labours of Columella, Varro, Seneca, Athenæus, and Oppian, yet the ancient authors who have treated most amply of their history and attributes, are Aristotle, Pliny, and Ælian. If the ancient annalist first named deserved the title above alluded to, so with equal propriety has Aristotle been named "the Father of Natural History." His descriptions, though often incomplete, are almost always exact. The general results with which we are now familiar in the works of our great physiological naturalists must not indeed be looked for; nor can it be denied that the merest tyro in anatomy would now be astonished at his doctrines relating to the structure and functions of the brain, which he regarded as a cold spongy mass, adapted for collecting and exhaling the superfluous moisture, and intended for aiding the lungs and trachea in regulating the heat of the body. He looked upon the heart as the seat of vital fire, and not only the fountain of the blood, but the organ of motion, sensation, nutrition, the seat of the passions, and the origin of the veins and nerves. He deemed that the blood was confined to the veins, while the arteries contained an aërial spirit; and by nerves he signified not only what are now so called, but also tendons and arteries, that is, any extended *string*-like portion which the name of νευρον literally implies. The heart, he alleged, had three cavities, and that in the larger animals it either communicated with the windpipe, or the ramifications of the pulmonary artery received the breath in the lungs and carried it to the heart, while respiration was effected by the expansion of air in the lungs, by means of internal fire, and the consequent irruption of the external air to prevent a vacuum. Digestion is a species of concoction or boiling, performed in the stomach, aided by the warmth of the neighbouring viscera! "It is perhaps impossible at the present day, when the investigation of Nature is so much facilitated by the accumulated knowledge of ages in every department of physical science, by the commercial relations existing between countries in all parts of the globe, by a tried method of observation, experiment and induction, and finally, by the possession of the most ingenious instruments, to form any adequate idea of the numerous difficulties under which the ancient naturalist laboured. On the other hand, he had this great advantage, that almost every thing was new; that the most simple observations correctly recorded, the most trivial phenomenon truly interpreted, became as it were his inalienable property, and was handed down to succeeding ages as a proof of his talents, a circumstance which must have supplied a great motive to exertion. The History of Animals is undoubtedly one of the most remarkable performances of which physical science can boast. It must not, however, be imagined, that it is a work which, replete with truth, and exhibiting the well-arranged results of accurate observation and laborious investigation, is calculated to afford material aid to the modern student. To him more recent productions are the only safe guides; nor is it until he has studied them, and interrogated nature for himself, that he can derive benefit from the perusal of the treatise which we now proceed to explain."[1] We shall here avail ourselves in part of the brief abstract of the writer just quoted.

The first book of Aristotle's History of Animals contains a short description of the parts of which their bodies are composed, and of the differences in the mode of life of living creatures. He asserts that man alone is capable of design, for although many other animals are endowed with memory and docility, none possesses the faculty of reflection but the human race. The sense of touch, he states, is common to all animals, and every living creature has a humour, blood, or sanies, the loss of which produces death. Every species that has wings has also two feet, and we know of no animal which flies only, as fishes swim, for such as have membranous wings likewise walk, and bats have feet, as have seals, although of an imperfect structure. In this chapter he divides animals into such as have blood, and such as have it not. Of the former (that is, the *red-blooded*), some want feet, others have two of these organs, others four. Of the latter (the *white-blooded*), many have more than four feet. Of the swimming animals, which are destitute of feet, some have fins, which are two or four, others none. Of the cartilaginous class, those which are flat have no fins, as the skate. Some of them have feet as the mollusca. Those that have a hard leathery covering swim with their tail. In regard to the mode of production, some animals are viviparous, others produce eggs, some worms. Man, the horse, the seal, and other land animals, bring forth their young entire; as do likewise cetacea and sharks. Those which have blow-holes have no gills, as the dolphin and whale. Of the flying animals, some, as the eagle and hawk, have wings; others, in place of wings, have membranes, as the bee and the beetle; while others are furnished with a leathery expansion, as the bat. Such as have feathered or leathery wings have blood (that is, red blood); but those provided with membranous wings, as insects are without blood (*i. e.* are white-blooded). Although he had previously stated that every winged species has also feet, he now propones that such as fly with wings or leathery expansions, either have two feet or none; for, says he, it is reported that there are serpents of this kind in Ethiopia. Of flying bloodless animals, some have their wings covered by a sheath, as beetles, while others have no covering, and of these some have two, others four wings. Those which are of large size, or bear a sting behind, have four, but the smaller or stingless have two wings only. Those which have sheaths to their wings, have no sting; but those which have two wings are furnished with a sting in their forepart, as the gnat. Animals are also distinguished from each other, so as to form kinds or families. These, according to Aristotle, are quadrupeds, birds, fishes, and cetacea—all of which have (red) blood. Then there is another kind, covered with a shell, such as the oyster; and another, protected by a softer shell, such as the crab. Another kind is that of the mollusca, such as the cuttle-fish; and finally, the family of insects. All these latter kinds are destitute of (red) blood. Here, then, we have a general classification of animals, which it is important should be borne in mind by whoever follows historically the stream of zoology to later times, a stream which, resembling that of certain actual waters, will be found in its downward course not only occasionally to diminish, but sometimes altogether to disappear.

---

[1] Macgillivray's Lives of Zoologists, in *Edinburgh Cabinet Library*, vol. xvi. p. 57.

It has been well observed that these, and numerous other general aphorisms which we have omitted, are by no means so simple or so easily attained, as one might imagine after cursory perusal; and this will be the most readily admitted by him who possesses the most comprehensive view of the great series of animated life. This system of Aristotle, then, may be exhibited in its general features by the following form:—

Red-Blooded Animals.

QUADRUPEDS, SERPENTS, BIRDS, FISHES, CETACEA.

White-Blooded Animals.

TESTACEA, CRUSTACEA, MOLLUSCA, INSECTS.

It must not, however, be understood that Aristotle proposes any formal distribution of animals, for his ideas respecting families, groups, and genera, were extremely vague, and bear little or no relation to the views entertained in modern times. His Quadrupeds (and it is with them that we are at present mainly concerned), include both the modern Mammalia and the quadrupedal Reptiles. He divides them into those which are viviparous, and those which are oviparous; the former covered with hair, the latter with scales. Serpents are also scaly, and, excepting the viper, oviparous. Yet all viviparous animals are not hairy, for, he observes, some fishes likewise bring forth their young alive. In the great family of viviparous quadrupeds there are also many species (or genera), such as man, the lion, the stag, and the dog, and he mentions as an example of a natural genus those animals which possess a mane, as the horse, the ass, the mule, and the wild ass of Syria, which are several distinct species, but together constitute a genus or family.[1]

In his second book Aristotle enters more into minute details, many of which are curiously accurate, while others are as singularly erroneous. An instance of the latter we meet with at the commencement, when he asserts that the neck of the lion has no vertebræ, but consists of a single bone. In speaking of members, he takes occasion to describe the proboscis of the elephant, and to enter generally into the history of that gigantic quadruped. He describes the buffalo and the camel, and in regard to the latter, he mentions both the Arabian and the Bactrian kinds. He next discusses the subject of claws, hoofs, and horns, and states that some quadrupeds have many toes, as the lion, while others have the foot divided into two, as the sheep, or composed of a single toe or hoof, as the horse. His general aphorisms on the subject of horns are wonderfully accurate. He states that most (he might have said all) animals furnished with them have cloven hoofs, and that no single-hoofed animal has two horns. He might have added, "nor even one." He next treats of teeth, which, he says, are possessed by all viviparous quadrupeds. Some have them in both jaws, others not; for horned animals have teeth in the lower jaw only, the front ones being wanting in the upper. Yet all animals which have no teeth above are not horned—the camel, for example. Some have projecting teeth, as the boar; others not. In some the teeth are jagged, as in the lion, panther, dog; in others even, as in the horse and cow. No animal has horns and protruded teeth; nor is there any having jagged teeth that has either horns or projecting teeth; but the seal has them all jagged, because it partakes of the nature of fishes, which possess that peculiarity. His remarks on the shedding of teeth are, however, erroneous, and his account of the hippopotamus is inaccurate in almost every particular. But in treating of monkeys he notices their great resemblance to the human race, the peculiar formation of their hind feet, and their perfect fitness to be used as hands. He then gives a general account of oviparous quadrupeds, and next proceeds to that of birds and fishes; but with none of these departments are we at present concerned.

Aristotle's third book is chiefly what may be called physiological. His fourth treats of those animals which he regards as destitute of blood; but even here we find interspersed various interesting and accurate observations on the higher classes. Thus he enumerates the organs of sensation, stating that man, and all the red-blooded and viviparous animals, possess five senses, although in the mole vision is defective. Yet he pretty correctly describes the eye of that subterranean dweller, shewing that although it is covered by a thickish skin (it is not of course so covered, though the aperture is small), it presents a conformation similar to that of other animals, and is furnished with a nerve from the brain. He says that all viviparous quadrupeds not only sleep but dream; but that it is uncertain whether the oviparous ones indulge in dreams, although they sleep. The fifth, sixth, and seventh books are occupied by the subjects of generation and parturition, and the eighth relates to the food, actions, migrations, and other circumstances in the history of animals. The ninth contains a multitude of topics not apparently at all related to each other, but which have in some way successively suggested themselves to the mind of the author. It is indeed believed that whatever remains to us of Aristotle's History or Animals may be looked upon as fragmentary; but in whatever light it may be viewed, it cannot be otherwise regarded than as entirely deficient in method. We continually meet with the most abrupt transitions, the subject more immediately at first in view being seemingly lost sight of for the sake of indulging in digressions foreign to its nature, and we frequently find a circumstance repeated. "This work resembles the rude notes which an author makes previous to the final arrangement of his book; and such it may possibly have been. Of descriptions properly so called there are few, those of the elephant, camel, bonasus, crocodile, chameleon, cuckoo, cuttle-fish, and a few others, being all that we find."[2] It cannot, however, be denied, that notwithstanding his numerous imperfections, he did much both for anatomy and natural history, "and more, perhaps," says Dr Barclay, "than any other of the human species, excepting such as a Haller or Linnæus, could have accomplished in similar circumstances."[3] The great importance justly attached to his writings as the founder of natural history, has induced us to present a more extended sketch of his views and doctrines than we can afford to other ancients. In our remaining notices we shall therefore be extremely brief.

Nearly three centuries and a half elapsed between the death of Aristotle and the birth of Pliny, who came into the world during the reign of Tiberius, and in the twentieth year of the Christian era. He was a voluminous compiler of all that was known during his own time, and although of less accurate observation, and of more defective judgment than his great predecessor, his works are extremely curious, and of considerable value in their way. His Natural History was his latest work, and unfortunately it is the only one which has descended to the present times. It was composed, according to his own statement, of extracts from more than 2000 volumes, written by authors of all kinds, and is in truth not so much a treatise on what we now term Natural History, as a relation of all that was known (and of not a little that was imagined) concerning animals, vegetables, the mineral kingdom, the "great globe itself," agriculture, commerce, medicine, and the arts. It is divided into thirty-seven books, the eighth of which consists of notices not only regarding our mammalia proper, such as elephants, lions, tigers, panthers, camels, cameleopards, rhinoceroses, and others, but also touches on the history of dragons, serpents, and reptiles. As an exposition of natural history, strictly so called, the work is in truth of little real interest, and of no utility, and we need scarcely say that every principle of natural arrangement is utterly unknown, or disregarded.

---

[1] *Ibid.* pp. 58-62.

[2] Loc. cit. p. 72.

[3] *On Life and Organization.* The best edition of the Πεϱι Ζωων ʽΙϛοϱια is that of Schneider, himself a great Grecian, and an accomplished naturalist. 4 vols. 8vo, Leipsic, 1811

The only other ancient naturalists whom we shall here name are Ælian and Oppian. The former, surnamed by reason of the sweetness of his style the Honey-tongued, flourished in the latter part of the second century, and wrote a history of animals in Greek, which abounds in foolish fables; the latter was a poet, of the early part of the third century, who is said to have received from Caracalla a golden crown for every line. Besides his works on fishing and falconry (the latter lost), he composed certain books on hunting (Cynogeticon), which, with the others, are probably still consulted by the curious, although we cannot pledge ourselves to their in any way advancing the student's knowledge of the mammiferous tribes.

When the darkest ages began to pass away, that is, when a lengthened period was concluding, during which, so far as can now be ascertained, the European mind does not seem to have been successfully exercised either in science or literature (excepting chiefly what was gained in the one from the Arabian writers, in the other from the legends of the Provençal Troubadours), we begin again to perceive the emanation of a feeble light. The expression, perhaps, should be qualified by considering the disadvantages of early writers,—their ignorance of anatomy,—and, for aught we know, the non-existence of museums. Albertus Magnus flourished during the greater period of the thirteenth century, and composed, among innumerable other works, a History of Animals. It is a remarkable production for its time. The author lived long at Cologne, where he is said to have miraculously raised flowers in winter, to please William Count of Holland. Another of his wonderful feats was the construction of a speaking automaton, which, however, was one day knocked on the head by Thomas Aquinas, the angelical doctor, who deemed it an agent of the devil. From these facts we ought probably to infer, that he possessed no mean skill in horticulture, and was an adept in mechanical philosophy. He is said, by some, to have derived his latinized name of Magnus, not so much from the greatness of his learning and celebrity, as because his family name in Dutch was *Groot.* Yet none of the Counts of Bollstadt, to whom he was akin, seem ever to have borne such name. In the greater proportion of his works, he appears either as a commentator on Aristotle (he is alleged to have been no great Grecian, and to have studied the Stagyrite chiefly through the medium of a Latin translation), or as a compiler from the Arabian writers. His History of Animals is mainly composed from Aristotle, Pliny, and Ælian. "He was a man," says Sir Thomas Browne, "who much advanced their opinions by the authoritie of his name, and delivered most conceits, with strickt enquirie into few."

Passing over about two hundred years, we have next to name some celebrated writers of the sixteenth century. Old Conrad Gesner, as we are accustomed to call him, died in the prime of life of a pestilential disease, in the year 1565. He was a native of Zurich, in Switzerland, and a very voluminous author. His only work which falls within our present cognisance is his History of Animals, which consists of five books, forming several folio volumes, the last of which was published posthumously, more than twenty years after his decease. They are adorned with numerous wooden cuts, which, as may be supposed, are more curious than accurate. This extraordinary compilation contains a critical review of whatever had been previously effected in zoology, but is itself principally composed of extracts from ancient writers. A portion of it was translated into English by Topsell, under the title of a "History of Four-footed Beasts and Serpents." Gesner's writings were long held in the highest estimation. Haller called him *Monstrum Eruditionis*, and his works on Natural History certainly contain a sufficiency of learning, and not a few monstrosities. He is said to have been the earliest individual who, being short-sighted, used the artificial advantage of concave glasses.

During the same century flourished (to use an accustomed term, although we regret to say, that, in regard to naturalists, it admits of a varied, and sometimes very doubtful interpretation) four other naturalists, all, in their way, entitled to the name of great; we allude to Pierre Belon, Hippolito Salviani, Guillaume Rondelet, and Ulysses Aldrovandi. The first three devoted themselves chiefly to fishes, and were, in fact, the founders of modern Ichthyology; the last named was more excursive and extended in his range. Bayle indeed has remarked, that antiquity does not furnish us with an instance of a design so extensive, and requiring such an amount of labour, as that of Aldrovandus. He truly far surpasses Pliny, both in length and verbosity. His works amount to thirteen volumes folio, only four of which (those on birds and insects) seem to have been published during his own life. The volume on "Quadrupeds which divide the hoof," was first digested by Cornelius Uterverius, and afterwards by Thomas Dempster, a Scotchman, professor at Bologna, and published in 1621. That on "Quadrupeds which do not divide the hoof," was likewise digested by Uterverius, and made its appearance in 1613. The volume on "Quadrupeds with toes or claws," as well as that on Monsters, was compiled from the manuscripts by Ambrosinus. The whole were afterwards reprinted at Frankfort, although it is now difficult to obtain a uniform edition. "Aldrovandus," says the Abbé Gallois, "is not the author of several books published under his name; but it has happened to the collection of natural history, of which those books are part, as it does to those great rivers which retain, during their whole course, the name they bore at their first rise, though, in the end, the greatest part of the water which they carry into the sea does not belong to them, but to other rivers which they receive; for, as the first six volumes of this great work were by Aldrovandus, although the others were composed since his death by different authors, they have still been attributed to him, either because they were a continuance of his design, or because the writers of them used his memoirs, or because his method was followed, or, perhaps, that these last volumes might be the better received under so celebrated a name." Aldrovandus is usually regarded as an enormous and insatiable compiler, without much taste or genius (the latter attribute, fortunately for encyclopædists, being not altogether essential to such an occupation), and seems to have borrowed largely, both as regards plan and materials, from his predecessor Gesner. Buffon says with great truth, that, if all that is useless or unnecessary were expunged from his works, they might be reduced to a tenth of their bulk; but we fear it may be added, with equal truth, that, if the same operation were performed on every author, not a few would be found to yield not even that priestly proportion. It is certain, however, that when

Aldrovandus treats of cocks or oxen, he does in no measure restrain himself to their natural history properly so called, but he tells us of all that the ancients have thought of them, of all that has been imagined of their virtues or their vices, their courage or character, all the miracles with which they have been connected, all the superstitions of which they have been the subject, all the comparisons which they have furnished to poets, all the attributes with which various nations have endowed them, as well as the hieroglyphics, or armorial bearings, in which they are represented; in short, of every thing that can be found or fancied in the history of cocks or oxen. It must be added, however, that, notwithstanding (possibly in consequence of) his endless redundancy, he is often extremely exact in many important particulars; and, although Baron Cuvier calls his compilation a troublesome and indigested mass, yet we know of more than one who has found it both curious and instructive. Aldrovandus, although of noble birth, and originally of prosperous fortunes, is said to have died blind in an hospital in Bologna. It was this melancholy recollection which, coming across our mind at the commencement of the present paragraph, induced us to qualify the meaning of the term *flourished*.

Notwithstanding the voluminous labours of the authors hitherto alluded to, little or no advance had been made in systematic zoology. It is indeed surprising, that, endowed with so much learning, and of course with energy and perseverance as its sources, none of these observers should have seen natural objects in the light in which they at present appear, even to the uninstructed; for the most ignorant amongst us would scarcely now arrange all mammiferous land animals and lizards in the same natural group, simply because they are characterized in common by the possession of four legs. But great advances were made in the course of the ensuing or seventeenth century. One of the earliest, and, we fear, also one of the least successful zoologists of this period, was John Johnston, descended no doubt originally from a Scottish family, but born near Lissa, a city of the district of Posen in Poland, in the year 1603. That portion of his "Historia Animalium" which treats of quadrupeds, was published at Frankfort-on-the-Maine in 1652. The plates, engraved by Matthew Merian, exhibit some improvement on those of Gesner and Aldrovandus, but the letter-press must share with theirs in the character of being in a great manner an uncritical compilation. We here pass unwillingly the great names of Redi and Swammerdam, neither of whom wrote on quadrupeds, although the physiological observations of the one, and the surprising and hitherto unrivalled researches in insect anatomy of the other, have rendered their names immortal, and, by the philosophical and inductive spirit by which they were respectively conducted, no doubt materially contributed to inspire a better and more original habit of observation than had hitherto prevailed.

The British naturalist justly regards with pride the high station occupied, towards the conclusion of the century, by the illustrious John Ray. His "Synopsis Methodica Animalium Quadrupedum, et Serpentini Generis," was published in 1693, and besides containing a systematic classification of these creatures, it describes their external forms and internal structure, and illustrates their instinctive habits by many important and interesting observations. Indeed, there are few departments of natural history which did not receive improvements from his pen. He is termed by Baron Cuvier "le premier véritable méthodiste pour le règne animal, guide principal de Linnæus dans cette partie." The great Swedish naturalist was indeed deeply indebted to Ray, and a careful and comparative perusal of the *Synopsis Quadrupedum* and of the early editions of the *Systema Naturæ*, certainly inspires a wish that the obligation had been more warmly acknowledged. The era in which Ray flourished has been justly described as the dawning of our golden age in natural history. "The peculiar character of his works," says Cuvier, "consists in clearer and stricter methods than those employed by any of his predecessors, and applied with more constancy and precision. The divisions which he has introduced into the classes of quadrupeds and birds have been followed by the English naturalists almost to our own day; and we find very evident traces of his system of birds in Linnæus, Brisson, Buffon, and in all the authors who have treated of that class of animals." We have already alluded, in our brief notice of preceding writers, to the singular absence of all effort to illustrate even the most familiar phenomena by any approach to actual observation; and this, we think, constitutes one of the great merits of Ray, that, with sufficient learning to appreciate and report the recorded studies of his predecessors, he yet looked abroad on nature with an eye of admiration and of love, from whence resulted a freshness and originality, for which we look in vain in many bulkier volumes, both of prior and of later times. "His varied and useful labours," observes the author of a recent memoir, "have justly caused him to be regarded as the father of natural history in this country; and his character is, in every respect, such as we should wish to belong to the individual enjoying that high distinction. His claims to the regard of posterity are not more founded on his intellectual capacity, than on his moral excellence. He maintained a steady and uncompromising adherence to his principles, at a time when vacillation and change were so common as almost to escape unnoticed and uncensured. From some conscientious scruples, which he shared in common with many of the wisest and most pious men of his time, he did not hesitate to sacrifice his views of preferment in the church, although his talents and learning, joined to the powerful influence of his numerous friends, might have justified him in aspiring to a considerable station. The benevolence of his disposition continually appears in the generosity of his praise, the tenderness of his censure, and solicitude to promote the welfare of others. His modesty and self-abasement were so great, that they transpire insensibly on all occasions; and his affectionate and grateful feelings led him, as has been remarked, to fulfil the sacred duties of friendship even to his own prejudice, and to adorn the bust of his friend with wreathes which he himself might have justly assumed. All these qualities were refined and exalted by the purest Christian feeling, and the union of the whole constitutes a character which procured the admiration of contemporaries, and well deserves to be recommended to the imitation of posterity."[1] Ray was born at Black Notley, in Essex, in 1628, and died at the same place in 1705.

The greatest naturalist who was, as it were, intermediate between Ray and Linnæus, or at least whose life embraced the death and old age of the one, and the birth and manhood of the other, was the celebrated French entomologist Réaumur. He was born at Rochelle in 1683, and died in 1757. His well-known *Memoires* on insects, are among the most valuable contributions which have ever been made to that department of science; but, as he did not write on mammiferous animals, we should not have introduced his name in this place, had he not been among the first in France to form an extensive museum, containing both quadrupeds and birds, and which is known to have afforded materials for the formation of M. Brisson's works.

We now arrive at the memorable epoch of Linnæus, that immortal and unrivalled naturalist, whose life and labours are now so well known, and so universally appreciated, that we deem it needless to indulge in any observations on the subject. He was born at Rashult, in the province of Smaland, in Sweden, on the 23d of May 1707, and, after reconstructing the whole arrangement of nature, inventing an unthought-of nomenclature, and bestowing upon both the organic kingdoms a lucid order which, but for him, they certainly would not have yet possessed, he died at Upsal on the 10th of January 1778. We shall merely add his curious and characteristic description of himself, substituting the pronoun "I" for the "He" of the original. "My head was prominent behind, and transversely depressed at the lambdoid suture. My hair was white in infancy, then brown, in old age somewhat grey. My eyes were of a hazel hue, vivacious and penetrating, with a remarkable power of vision. My forehead became wrinkled in after life. I had an obliterated wart on my right cheek, and another on the same side of my nose. My teeth were ineffective, having become unsound in early life from hereditary toothach. My mind was quick, easily moved to anger, joy, or sadness, quickly appeased; in youth hilarious, not torpid in age; in business extremely prompt. My gait was light and active. I committed all household cares to my wife, being myself concerned solely with the productions of nature. I brought to a conclusion whatever I commenced, and during a journey I never looked backwards." The writings of Linnæus were extremely numerous, but we have here to do only with his arrangement of the mammiferous tribes, which introduced so many clear and precise elements into what had before been little else than a chaos of darkness and uncertainty, that but few and trifling amendments have since been effected in that branch of zoology up to the present day. The first edition of his great work the "Systema Naturæ," was printed at Leyden in 1735, and consisted of only a few folio pages. Numerous editions were called for during the lifetime of the author. That usually called the twelfth (it is believed to be in reality the fifteenth) is the best, and the last which received Linnæus's own improvements. It was published at Stockholm in 1766, and from it we have made up the following abstract of his arrangement of the class Mammalia.[1]

---

[1] Memoir of Ray, in *Naturalist's Library*, Entomology, vol. ii. p. 69.

Order I.—PRIMATES.

Homo, Man: two species!
Simia, Baboons and monkeys: thirty-three species.
Lemur, Macauco: five species.
Vespertilio, Bats: six species.

Order II.—BRUTA.

Elephus, Elephant: one species.
Trichechus, Walrus: two species.
Bradypus, Sloth: two species.
Myrmecophaga, Ant-eater: four species.
Manis, Manis: two species.
Dasypus, Armadillo: six species.

Order III.—FERÆ.

Phoca, Seal: three species.
Canis, Dog, wolf, fox, &c.: nine species.
Felis, Lion, tiger, cat, &c.: seven species.
Viverra, Civet: seven species.
Mustela, Marten, polecat, &c.: eleven species.
Ursus, Bear: four species.
Didelphis, Opossum: five species.
Talpa, Mole: two species.
Sorex, Shrew: five species.
Erinaceus, Hedgehog: three species.

Order IV.—GLIRES.

Hystrix, Porcupine: four species.
Lepus, Hare: four species.
Castor, Beaver: three species.
Mus, Rats and mice: twenty-one species.
Sciurus, Squirrel: eleven species.
Noctilio, A kind of bat: one species.

Order V.—PECORA.

Camelus, Camel, dromedary, &c.: four species.
Moschus, Musk deer: three species.
Cervus, Deer: seven species.
Capra, Goat: twelve species.
Ovis, Sheep: three species.
Bos, Oxen: six species.

ORDER VI.—BELLUÆ.

Equus, Horse, ass, zebra: three species.
Hippopotamus: one species.
Sus, Hog: five species.
Rhinoceros: one species.

Order VII.—CETE.

Monodon, Narwhal: one species.
Balæna, Whale: four species.
Physeter, Cachalot: four species.
Delphinus, Dolphin: three species.

The principal objection which has been found to the preceding system is derived from the alleged unnatural separation of the Orders BRUTA, PECORA, and BELLUÆ, which are chiefly detached portions of the great Order UNGULATA of Ray, and which even Aristotle had placed in juxtaposition. They have, therefore, after the ejection of certain genera into other orders, been again brought together by Baron Cuvier, in his sixth and seventh primary divisions. Yet we cannot but wonder, that with a knowledge of the nature or existence of not more than about 230 mammiferous animals (probably about a fifth part of those with which we have now some acquaintance) Linnæus should have been able to construct such a system; for it is admitted that his *genera* are for the most part natural, in as far as they contain assemblages of species which in the majority of cases have been preserved in more recent systems, although under higher denominations, and split into minor divisions. It is also admitted that, with certain exceptions (which chiefly concern the Order BRUTA), the internal contents of the orders themselves are natural groups.[2] At all events, the influence exercised by the Linnæan system was immense and immediate, and has proved continuous and abiding. Indeed, we have already had occasion elsewhere to remark,[3] that, with the exception of the purely artificial classification of Klein, and the multiplied orders of Brisson and Vicq-d'Azyr, all the systems which have appeared since the middle of the last century are indebted more or less to the labours of the immortal Swede, and may be valued almost exactly in proportion to their share in the *lucidus ordo* of the Linnæan System. Of this no one need doubt who inclines to compare with the *Systema Naturæ* of 1766, the *Systema Regni Animalis* of Erxleben (1777), the *Prodromus Methodi Animalium* of Storr (1780), or the *Elenchus Animalium* of Bodaert (1787). Nor can it have escaped the notice of the critical observer, that after thirty years of profound and philosophical research into the mysteries of the animal kingdom, the most accomplished zoologist and anatomist of the age should have finally reverted to a closer approximation to the Linnæan system, than had characterized his views at any former period of his brilliant career. When Baron Cuvier first made known, conjunctly with M. Geoffroy (in 1797), his new classification of mammiferous animals, his numerous genera were contained under no less than fourteen different orders. Just thirty years afterwards (in 1817), he published his *Règne Animal*, with many improvements in the composition and arrangement of the minor divisions, and with the addition of the Order of which he is himself so bright an ornament, but composed, so far as the Mammalia are concerned, of primary divisions exactly the same in number, and nearly the same in nature, as those divulged and established by Linnæus himself at least sixty years before. That this is the admitted opinion of many of Cuvier's own countrymen and most devoted admirers, may be inferred from the following passage, which relates to Linnæus:—"Aussi toutes ses coupes ont-elles été généralement adoptées. Tous ses ordres sont encore admis aujourd'hui par la plupart des naturalistes modernes, et particulièrement par Cuvier, qui seulement a substitué aux noms de Linné presque tous peu susceptibles d'être traduits en français, ceux de *Quadrumanes*, d'*Edentés*, de *Carnassiers*, de *Rongeurs*, de *Ruminans*, de *Pachydermes*, et de *Cétacés*. Enfin parmi ces genres (those of Linnæus) ceux meme qu'on a été obligé de subdiviser, se retrouvent encore conservés dans les classifications les plus récentes, *où elles formes des familles naturelles*. C'est ainsi, par exemple, que l'ordre des Quadrumanes comprend deux grandes familles, les Singes et les Lémuriens, qui correspond exactement au genre *Simia* et au genre *Lemur* de l'illustre legislateur de la Zoologie."[1]

---

[1] A greatly enlarged but inaccurate edition, known as the thirteenth, was compiled by Gmelin, and published at Leipsic in 1788. Dr Turton's English edition, London 1806, is a translation of that of Leipsic.

[2] Swainson *On the Geography and Classification of Animals*, p. 145.

[3] See ANIMAL KINGDOM of this Work, vol. iii. p. 182.

We have entered into these details (which many may deem unnecessary), in consequence of what we sometimes perceive of a spirit adverse to the philosophical character of the great Swedish naturalist. Delighting as we do to witness whatever of talent and ingenuity is being exercised in the development of the so-called Natural System (and that every age will furnish fresh materials towards the more satisfactory solution of that great and mysterious problem we cannot doubt), we yet desire it should be borne in mind how vast are the benefits which Linnæus has conferred on natural history, and how, but for him, we should, in all likelihood, have been still straying infinitely farther from the truth,

> "And found no end, in wandering mazes lost."

All who are in any way conversant in the science, know how admirable was his tact in the discovery of the minor natural groups, though he may have frequently failed in their combination. But whatever view we may take of methods and systems, it can scarcely be doubted that no one has contributed such valuable materials for the various and not seldom discordant theorists to work upon. Let those who find these materials in any great measure intractable, bethink themselves occasionally of a homely Scotch proverb, that "a bad reaper never had a good hook."

Although Buffon cannot be regarded as a systematic author, yet his writings have exercised so strong and beneficial an influence on natural history, that we cannot pass his name unnoticed in our cursory sketch. "Il restera toujours," says Baron Cuvier, "l'auteur fondimental pour l'histoire des quadrupèdes;" and we doubt not that the splendour of his style was among the earliest and most forcible of those exciting causes which led to a general interest in this delightful study. By bringing into play a finer combination of literary and scientific attainments, a more discursive and imaginative style, and perhaps a greater power of actual intellect than had previously fallen to the lot of (at least the modern) naturalist, he relieved the science of zoology from the undeserved opprobrium of being regarded as the pursuit of inferior capacities; and by embodying his thoughts in language as attractive as had ever been employed to give expression to the workings of the human mind, even in the higher departments of literature, he gained many proselytes among those who had hitherto viewed the subject, and all its barren technicalities, with coldness if not disgust. He has no doubt exposed himself to the reproach of having utterly disregarded the necessity, in so complex and multifarious a study, of a rigorous nomenclature, and a methodised arrangement, as well as of having introduced many grave errors, not the less dangerous and deceptive that they bear the impress of genius. Many of his descriptive sketches must be regarded rather as vivid representations drawn from an exuberant and irrepressible imagination, than as accurate portraitures deduced from the observance of nature. It cannot be denied, however, that many of his general observations are extremely important, and he was among the first to call attention to the interesting subject of zoological geography, by his comparative remarks on the quadrupeds of the old world and those of America.

As it is not our intention to exhibit in detail the features of any but the more important and influential systems, we shall here briefly illustrate the progress of the science by enumerating the amount of species described by certain well-known authors, who were either contemporaneous with, or the immediate successors of Linnæus. Brisson describes 275;[2] Erxleben, 345;[3] Pennant, 412;[4] Boddaert, 344;[5] Buffon, 333 (including his supplements, and the Cetacea of La Cepede);[6] Gmelin, 440;[7] and Vicq. d'Azyr, 363.[8] Among these authors, as M. Desmarest has observed,[9] such as have indicated the highest amount of species, have been the least critical and distinctive in their enunciation of their characters. The observation applies particularly to Pennant, Gmelin, Boddaert, and Vicq. d'Azyr, who, whatever may have been their other merits (and those of our countryman were of the highest order), were in no way distinguished for a severe revisal of the facts on which they founded. It has been calculated, that, notwithstanding the additional zeal with which the natural history of quadrupeds has been of late pursued, about an eighth part of the species described by these authors remain undetermined even at the present day.

The system of Illiger departs considerably from that of Linnæus. The Berlin Professor, of whose capacity and accomplishments no one doubts, has been reproached, and not unjustly, for a needless disregard of the nomenclature of his predecessors and contemporaries, and for a love of change, which induced a French critic to accuse him,—"d'avoir inventé beaucoup plus de mots qu'il n'a fait de travaux utiles." Nevertheless, his system, which contained, at the time of its appearance (in 1811), the indication of several new and judicious genera, has been sufficiently influential to induce us to present it to our readers. He divides the entire mammiferous class into fourteen orders, containing thirty-nine families, and a hundred and twenty-five genera, as follows. We add the name of a well-known species of each genus, with a view to illustrate the nature of the group.

[9] *Mammalogie* (Avertissement), p. 7.

Illiger defines Mammalia as vertebrated animals, breathing by means of lungs, with warm red blood, a heart with two ventricles and two auricles, a diaphragm, mammæ, a skin either hairy or bald, viviparous, giving milk.

Synopsis of ILLIGER'S *Orders, Families, and Genera.*

ORDER I. ERECTA.

Family 1. *Erecta.*

1.	Genus Homo.	H. sapiens, L.

ORDER II. POLLICATA.

Family 2. *Quadruma.*

2.	Simia, Cuv. Orang.	S. Troglodytes.
3.	Hylobates (υλοβατης, per sylvas gradiens). Gibbon.	S. Lar, L.
4.	Lasiopyga (λασιος, villosus, πυγη, anus).	S. nemea, L.
5.	Cercopithecus. Guenon or Monkey.	S. nasica.
6.	Cynocephalus. Ape, baboon.	S. silenus, L.
7.	Colobus (ϰολοβος, mutilatus).	S. ferruginea.
8.	Ateles.	S. paniscus, L.
9.	Mycetes (μυϰητης, mugiens).	S. Beelzebub, L.
10.	Pithecia.	S. pithecia, L.
11.	Aotus.	S. trivirgata.
12.	Callithrix.	S. capucina, L.
13.	Hapale (απαλος, mollis).	S. rosalia, L.

Family 3. *Prosimii.*

14.	Lichanotus (λιχανος, digitus, index). Indri.	Lemur indri, L.
15.	Lemur . Maki.	L. mongoz, L.
16.	Stenops (στενος, angustus, ωψ, oculus). Lori.	L. tardigradus, L.

Family 4. *Macrotarsi.*

17.	Tarsius. Tarsier.	Didelphis macrotarsius, L.
18.	Otolicnus (ωτολιϰνος, auriculis magnis). Galago.	Lemur Galago.

Family 5. *Leptodactyla.*

19.	Chiromys. Aye aye.	Sciurus madagascariensis, L.

Family 6. *Marsupialia.*

20.	Didelphis. Opossum.	Didelphis marsupialis, L.
21.	Chironectes (χειϱ, manus, νηϰτης, natator).	Lutra minima.
22.	Thylacis (ϑυλαξ, saccus, marsupium). Perameles.	Didelphis obesula.
23.	Dasyurus.	D. viverrina.
24.	Amblotis (αμβλωσις, abortus). Wombat.	Wombatus fossor.
25.	Balantia (βαλαντιον, marsupium). Phalangista. C.	Didelphis orientalis, L.
26.	Genus Phalangista.	Didelphis petaurus.
27.	Phascolomys.	Phasc. fusca.

ORDER III. SALIENTIA.

Family 7. *Salientia.*

28.	Hypsiprymnus (υψιπϱυμνος, parte postica elevata). Potoroo.	Did. potoru.
29.	Halmaturus (αλμα, saltus, ȣϱη, cauda). Kangaroo.	Didelphis gigantea, L.

ORDER IV. PRENSICULENTIA.

Family 8. *Macropoda.*

30.	Dipus. Gerboa.	Dipus sagitta, L.
31.	Pedetes (πηδητης, saltator).	D. cafer, L.
32.	Meriones (μεϱος, femur).	D. tamaricinus, L.

Family 9. *Agilia.*

33.	Myoxus. Dormouse.	Myoxus glis, L.
34.	Tamias (ταμιας, promus, condus).	Sciurus striatus, L.
35.	Sciurus. Squirrel.	Sc. vulgaris.
36.	Pteromys. Flying squirrel.	Sc. volans.

Family 10. *Murina.*

37.	Arctomys. Marmot.	Arct. marmota, L.
38.	Cricetus. Hamster.	Mus cricetus, L.
39.	Mus. Rat, mouse.	M. decumanus, L.
40.	Spalax.	M. typhlus, L.
41.	Bathyergus (βαϑυεϱγειν, terram profunde laborare).	M. maritimus, L.

Family 11. *Cunicularia.*

42.	Georichus (γεωϱυχος, qui terram fodit). Mole rat.	M. capensis, L.
43.	Hypudæus (υπȣδαιος, subterraneus). Field-mouse.	M. arvalis, L.
44.	Fiber. Musk beaver.	M. zibethicus, L.

Family 12. *Palmipeda.*

45.	Hydromys.	M. coypus, L.
46.	Castor. Beaver.	Castor fiber, L.

Family 13. *Aculeata.*

47.	Hystrix. Porcupine.	Hystrix cristata, L.
48.	Loncheres (λογχηϱης, qui lanceam fert).	Lonch. paleacea.

Family 14. *Duplicidentata.*

49.	Lepus. Hare.	Lepus timidus, L.
50.	Lagomys. Pica.	L. pusilla, L.

Family 15. *Subungulata.*

51.	Cœlogenys.	Cavia paca.
52.	Dasyprocta (δασυς, hirsutus, πϱωϰτος, anus). Agouti.	C. agouti, L.
53.	Cavia. Guinea-pig, or Cavy.	C. aperea, L.
54.	Hydrochærus. Capybara.	C. capibara.

ORDER V. MULTUNGULA.

Family 16. *Lamnunguia.*

55.	Lipura (λειπουϱος, cui cauda deest).	Hyrax Hudsonius.
56.	Hyrax. Daman.	H. capensis.

Family 17. *Proboscidea.*

57.	Genus Elephas. Elephant. .	E. indicus.

Family 18. *Nasicornia.*

58.	Rhinoceros. . . .	Rh. bicornis.

Family 19. *Obesa.*

59.	Hippopotamus. . .	Hip. amphibius, L.

Family 20. *Nasuta.*

60.	Tapirus. Tapir. . .	T. Americanus.

Family 21. *Setigera.*

61.	Sus. Hog.	Sus scrofa, L.

ORDER VI. SOLIDUNGULA.

Family 22. *Solidungula.*

62.	Equus. Horse, &c. .	E. caballus, L.

ORDER VII. BISULCA.

Family 23. *Tylopoda.*

63.	Camelus. Camel. . .	C. dromedarius, L.
64.	Auchenia (αυχην, collum),	C. llacma, L.

Family 24. *Devexa.*

65.	Camelopardalis. Giraffe.	C. giraffa.

Family 25. *Capreoli.*

66.	Cervus. Deer. . .	C. alces, L.
67.	Moschus. Musk. . .	M. moschiferus, L.

Family 26. *Cavicornia.*

68.	Antilope.	Antilope gnu, L.
69.	Capra. Goat, sheep. .	C. ibex, L.
70.	Bos. Ox.	B. urus, L.

ORDER VIII. TARDIGRADA.

Family 27. *Tardigrada.*

71.	Bradypus. Sloth. . .	B. tridactylus, L.
72.	Chælepus (χωλοιπους, pede claudus). . . .	B. torquatus.
73.	Prochilus (πϱοχειλος, labrosus).	B. ursinus.

ORDER IX. EFFODENTIA.

Family 28. *Cingulata.*

74.	Tolypeutes (τολυπευειν, conglomerare). . .	Dasypus tricinctus, L.
75.	Dasypus. Armadillo. .	D. sexcinctus, L.

Family 29. *Vermilinguia.*

76.	Orycteropus. . . .	Myrmecophaga capensis, L.
77.	Myrmecophaga. Anteater.	M. jubata, L.
78.	... Manis. Pangolin. . .	M. tetradactyla, L.

ORDER X. REPTANTIA.

Family 30. *Reptantia.*

79.	Tachyglossus (ταχυς, velox, γλωσσα, lingua). Echidna.	Myrm. aculeata, Shaw Echidna setosa, Cuv.
80.	Ornithorhynchus. .	Orn. paradoxus.

ORDER XI. VOLITANTIA.

Family 31. *Dermoptera.*

81.	Galeopithecus. Colugo.	Lem. volans. L.

Family 32. *Chiroptera.*

82.	Genus Pteropus. Ternate bat.	Vesp. vampyrus, L.
83.	Harpyia (avis fœda vultu humano mythologiæ).	Vesp. cephalotes, L.
84.	Vespertilio. Bat. . .	Vesp. murinus, L.
85.	Nycteris.	Vesp. hispidus, L.
86.	Rhinolophus, . . .	Vesp. ferrum equum, L.
87.	Phyllostomus, . . .	Vesp. spasma, L.
88.	Noctilio, ...	Vesp. leporinus, L.
89.	Saccopteryx (σακκος, saccus, πτεϱυξ, ala). .	Vesp. lepturus, L.
90.	Dysopes (δυσωπεω, horribili specie perterreo).	Vesp. molossus, L.

ORDER XII. FALCULATA.

Family 33. *Subterranea.*

91.	Erinaceus. Hedgehog.	E. europæus, L.
92.	Centetes (κεντεω, pungo). Tenrec.	E. ecaudatus, L.
93.	Sorex. Shrew. . . .	S. araneus, L.
94.	Mygale. Desman. .	S. moschatus, L.
95.	Condylura (κονδυλος, nodus, ουϱη, cauda). .	S. cristatus, L.
96.	Chrysochloris, . . .	S. auratus, L.
97.	Scalops.	S. aquaticus, L.
98.	Talpa. Mole. . . .	T. europæus, L.

Family 24. *Plantigrada.*

99.	Cercoleptes (κεϱκος, cauda, ληπτης, capiens). Potos.	Viverra caudivolva, L.
100.	Nasica. Coati. . .	V. narica, L.
101.	Procyon. Racoon. .	Ursus lotor, L.
101.	Gulo. Glutton. . .	U. gulo, L.
103.	Meles. Badger. . .	U. meles, L.
104.	Ursus. Bear. . . .	U. arctos, L.

Family 35. *Sanguinaria.*

105.	Megalotis (μεγας, magnus, ους, auris). Fennec.	Canis cerda, L.
106.	Canis. Dog, Wolf. .	C. lupus, L.
107.	Hyæna.	C. hyæna, L.
108.	Felis. Cat. . . .	F. leo, L.
109.	Viverra. Civet. . .	V. zibetha, L.
110.	Ryzæna (ϱυζειν, hirrire ut canis). . . .	V. tetradactyla, L.

Family 36. *Gracilia.*

111.	Herpestes (εϱπηστης, reptans). Ichneumon.	V. ichneumon, L.
112.	Mephitis.	V. putorius, L.
113.	Mustela. Weasel, Martin. . . , . . .	Mustela martes, L.
114.	Lutra. Otter. . .	L. vulgaris, L.

ORDER XIII. PINNIPEDIA.

Family 37. *Pinnipedia.*

115.	Phoca. Seal. . . .	Ph. jubata, L.
116.	Trichechus. Morse.	Tr. rosmarus, L.

ORDER XIV. NATANTIA.

Family 38. *Sirenia.*

117.	Manatus.	Trich. manatus australis, L.
118	Halicore (αλιος, marinus, κοϱη, puella). Dugong.	Trich. dugong, L.
119.	Rytina (ϱυτις, ruga).	Trich. manatus borealis, L.

Family 39. Cete.

120.	Genus Balæna. Whale. . .	B. mysticetus, L.
121.	Ceratodon. Narwhal	Monodon monoceros, L.
122.	Ancylodon (αγκυλος, incurvus, οδους, dens).	
	Anarnak, . . .	Mon. spurius.
123.	Physeter. Cachalot.	Ph. macrocephalus, L.
124.	Delphinus. Dolphin.	D. albicans, L.
125.	Uranodon (ουρανη, palmatum, οδους, dens).	D. butzkopf, L.

The student will not fail to perceive that many of these generic groups, indicated for the first time by Illiger, now form component parts of all our recent arrangements of the animal kingdom.

Although M. Desmarest's work on the Mammalia is one of great value to the student, his system of arrangement so closely resembles that of Baron Cuvier (which, with some modifications, we intend to follow in the present treatise), that its detailed exhibition would be here unnecessary. It bears the date of 1820–22, and certainly presents the most complete and accurate summary of the mammiferous tribes up to that period.[1] It may therefore be assumed as marking an epoch in the science, and as affording a useful point of comparison with preceding times. We have already mentioned that Linnæus was acquainted with not more than about 230 mammiferous animals, and have likewise exhibited the *totals* of his immediate successors. The entire number described by Desmarest is 849, partitioned as follows: Bimana, 1; Quadrumana, 141; Carnivora, 320 (subdivided into Cheiroptera, 97, Insectivora, 29, the true Carnivora, 147, and Marsupialia, 47); Glires, 149; Edentata, 24; Pachyderma, 55; Ruminantia, 97; Cete, 62. But of these 849 species, he marks about 145 with an asterisk, as being too obscurely known to be admitted with certainty to a distinct specific rank. There is also to be deducted 42 fossil species, which leaves 662 as the totality of living mammiferous animals of which we have a distinct knowledge, according to M. Desmarest. In regard to the general distribution of animals over the earth, our author gives the following numerical summary. South America, 181 species; North America, 54; common to Asia and America, 10; Northern Asia, 41; Europe, 88; Africa, 107; Madagascar and Mascareigne, 29; Southern Asia and Ceylon, 78; Indian Archipelago, 51; New Holland and Van Diemen's Land, 33. About 30 cetacea and seals inhabit the northern seas, 14 those of the south, and about 28 the waters of the intermediate regions. The number of terrestrial species subjected to the service of the human race is 13, and out of that limited amount above 112 *varieties* have been produced by the effects of domestication. We may here remark, that from the time of Daubenton (1782)[2] to that of Desmarest (1822), exactly forty years elapsed, and that during that period the amount of known mammiferous animals was more than doubled. During the subsequent fourteen years, we doubt not that the zeal of our other living naturalists has effected a proportional increase.

M. Temminck is chiefly known as a distinguished ornithologist. To an excellent work on certain mammiferous tribes,[3] he has, however, prefixed a "Tableau Methodique" of the orders, genera, and sectional divisions, of the class Mammalia, with an (approximate) enumeration of the species contained in each. He asserts with confidence that these (in 1827) amount to 860 distinct and clearly ascertained kinds. We think it due to a naturalist to whom ornithology, especially that of Europe, stands so highly indebted, to present a view of the system of arrangement in accordance with which he has classed the quadrupeds in the National Museum of the Low Countries (Leyden).

ORDER I. BIMANA.

1. Genus *Homo*, Linn.

ORDER II. QUADRUMANA.

First Tribe. Ancient Continent.

1. *Simia*, Linn. Two species, and a third doubtful.
2. *Hylobates*, Illig. Four species distinctly known, and a fifth doubtful.
3. *Colobus*, Geoff. Two species.
4. *Semnopithecus*, F. Cuvier. Twelve species.
5. *Cercopithecus*, Briss. Composed of two sections, Cercopithecus proper (of which about 20 species), and Macacus (of which 10 species).
6. *Innuus*, Geoff. One species.
7. *Cynocephalus*, Briss. Nine species.

Second Tribe. New Continent.

8. *Mycetes*, Illig. Six distinct species, and one doubtful.
9. *Ateles*, Geoff.
10. *Cebus*, Erxleb. Amount difficult to determine, from confusion in synonymes, and variation in age and sex.
11. *Pithecia*, Geoff. Six or seven species.
12. *Lagothrix*, Geoff. Two species.
13. *Callithrix*, Cuv. Eight species.
14. *Hapale*, Illig. Fifteen or sixteen species.
15. *Nocthora*, F. Cuv. Three species.

Third Tribe. Lemuridæ.

16. *Otolicnus*, Illig. Three species ascertained.
17. *Tarsius*, Storr. One species.
18. *Stenops*, Illig. Five species.
19. *Lichanotes*, Illig. One species.
20. *Lemur*. Twelve species.
21. *Galeopithecus*. Two species.

ORDER III. CHEIROPTERA.

1. *Dysopes*, Illig. Eleven species known, and eight others indicated, besides a European species still obscure.
2. *Pteropus*, Briss. Seventeen species, of which one is probably nominal.
3. *Cephalotes*, Geoff. Two species.
4. *Stenoderma*, Geoff. One species.
5. *Mormoops*, Leach. One species.
6. *Noctilio*, Geoff. One species.
7. *Phyllostoma*, Geoff. Eleven or twelve species.
8. *Vampirus*, Geoff. Two or three species, of which only one is well determined.
9. *Glossophaga*, Geoff. Six species.
10. *Megaderma*, Geoff. Three species.
11. *Rhinolophus*, Geoff. Fourteen known and two doubtful species.
12. *Nycteris*, Geoff. Three species, of which one is rather doubtful.
13. *Rhinopoma*, Geoff. One species.
14. *Taphozous*, Geoff. Seven species.
15. *Emballonura*, Kuhl. Two species, and a third doubtful.
16. *Nycticejus*, Rafinesque. Eight species.
17. *Vespertilio*, Linn. Probably forty species, or upwards.

Order IV. Carnivora.

First Tribe. Insectivora.

1. Genus *Erinaceus*, Linn. Two well known species, and a third doubtful.
2. *Sorex*, Linn. Fourteen or fifteen species.
3. *Hylogale*, Temm. Three species.
4. *Mygale*, Cuv. Two species, and a third doubtful.
5. *Scalops*, Cuv. One or two species.
6. *Chrysochloris*, Cuv. One well known species.
7. *Condylura*, Illig. One or two species.
8. *Talpa*, Linn. Three species.
9. *Centetes*, Illig. Three species.

Second Tribe. Carnivora proper.

10. *Ursus*, Linn. Ten or eleven probably distinct species.
11. *Procyon*, Storr. Two species.
12. *Nasua*, Storr. Two species.
13. *Cercoleptes*, Illig. One species.
14. *Taxus*, Linn. Two species.
15. *Mydaus*, F. Cuv. Two species.
16. *Gulo*, Retsi. Five or more species, some of which but ill determined.
17. *Arctictis*, Temm. One species.
18. *Paradoxurus*, F. Cuv. Six species.
19. *Mustela*, Linn. Twenty species ascertained, and others indicated.
20. *Lutra*, Briss. Six species.
21. *Mephitis*, Linn. Two species.
22. *Herpestes*, Illig. Eleven species.
23. *Ryzæna*, Illig. One species.
24. *Viverra*, Linn. Nine species known, and two more indicated.
25. *Canis*, Linn. Thirty species known, and several others indicated.
26. *Proteles*, J. Geoff. One species.
27. *Hyæna*, Briss. Two well known species, and a third indicated.
28. *Felis*, Linn. About thirty species known, besides several others not yet distinctly constituted.

Third Tribe. Amphibia.

29. *Phoca*, Linn. Fourteen or fifteen species known, besides a few which are doubtful.
30. *Otaria*, Peron. Six species, one of which is doubtful.
31. *Trichechus*, Linn. One species.

Order V. Marsupialia.

1. *Didelphis*, Linn. Twelve well known species, and three doubtful.
2. *Cheironectes*, Illig. One species.
3. *Phascogale*, Temm. Two species.
4. *Thylacinus*, Temm. One species.
5. *Dasyurus*, Geoff. Four species.
6. *Perameles*, Geoff. Two species.
7. *Phalangista*, Geoff. Eight species.
8. *Petaurus*, Shaw. Five species.
9. *Hypsiprymnus*, Illig. Two or three species.
10. *Halmaturus*, Illig. Eight species.
11. *Phascolarctos*, Blainv. One species.
12. *Phascolomys*, Geoff. One species.

Order VI. Glires.

1. *Castor*, Linn. Two species.
2. *Fiber*, Cuv. One species.
3. Genus *Hypudæus*, Illig. Amount doubtful.
4. *Lemmus*, Cuv. Probably eight species, three doubtful.
5. *Spalax*, Gulden. Probably three species.
6. *Echimys*, Geoff. Eight species.
7. *Myoxus*, Gmel. Six species.
8. *Myopotamus*, Commers. One species.
9. *Hydromys*, Geoff. Two species.
10. *Capromys*, Desmar. One species ascertained, another doubtful.
11. *Mus*, Linn. A numerous, badly arranged, and obscurely determined genus, of which the amount may be stated approximately at about forty species.
12. *Ascomys*, Lichten. One species.
13. *Bathiergus*, Illig. Two species.
14. *Pedetes*, Illig. One species.
15. *Dipus*, Gmel. Seven species, of which probably a few are merely nominal.
16. *Meriones*, Illig. Five or six species, besides those indicated by M. Rafinesque.
17. *Aulacodus*, Swind. One species.
18. *Arctomys*, Linn. Four well known species, and a like number doubtful.
19. *Spermophilus*, F. Cuv. Five species.
20. *Sciurus*, Linn. About thirty established species, and from eight to ten of doubtful indication.
21. *Pteromys*, Cuv. Eight well known species.
22. *Cheiromys*, Cuv. One species.
23. *Hystrix*, Briss. Four established species, and one doubtful.
24. *Sinœtherus*, F. Cuv. Two well determined species, and a third probable.
25. *Lepus*, Linn. Twelve species.
26. *Lagomys*, Geoff. Three species.
27. *Hydrochærus*, Briss. One species.
28. *Cavia*, Erxleb. Three species.
29. *Dasyprocta*, Illig. Four or five species.
30. *Cœlogenus*, F. Cuv. Two species.

Order VII. Edentata.

1. *Bradypus*, Linn. Three species.
2. *Dasypus*, Linn. Eight species, of which two are more or less doubtful.
3. *Orycteropus*, Geoff. One species.
4. *Myrmecophaga*, Linn. Four species, and two others of which the existence is probable.
5. *Manis*, Linn. Three species.

Order VIII. Pachydermata.

1. *Elephas*, Linn. Two species.
2. *Hippopotamus*, Linn. One species.
3. *Phascochæres*, F. Cuv. Probably two species.
4. *Sus*, Linn. About six species.
5. *Dicotyles*, Cuv. Two species.
6. *Rhinoceros*, Linn. Four or five species.
7. *Hyrax*, Herman. One species.
8. *Tapyrus*, Briss. Two species, and a third obscurely known.
9. *Equus*, Linn. Seven species.

Order IX. Ruminantia.

First Tribe. Without Horns.

1. *Camelus*, Linn. Two species.
2. *Auchenia*, Illig. Three species.
3. *Moschus*, Linn. Five species, one of which is doubtful.

Second Tribe. The Males Horned.

4. Genus *Cervus*, Linn. About twenty-four species known, besides a few others which are doubtful.

Third Tribe. Horns encased.

5. *Camelopardalis*. One species.
6. *Antilope*, Pallas. Between forty and fifty species are distinctly known, and there are indications of five or six other species.
7. *Catoblepas*, Ælien. Two species.
8. *Capra*, Linn. Five or six typical species, with numerous varieties.
9. *Ovis*, Linn. Six or seven distinct species, with numerous domestic races.
10. *Bos*, Linn. Nine distinct species, and many domestic varieties.

Order X. Cetacea.

First Tribe. Herbivora.

1. *Manatus*, Linn. Two species, and a third doubtful.
2. *Halicore*, Illig. One species.
3. *Stellerus*, Cuv. One species.

Second Tribe. Piscivora.

4. *Delphinus*, Linn. Fifteen or sixteen species are pretty accurately known, and about fourteen others are indicated, many of which are no doubt purely nominal.
5. *Monodon*, Linn. One well known species, and two or three others obscurely, and probably inaccurately indicated.
6. *Physeter*, Linn. Two species, better known than five or six others of which we have only vague indications.
7. *Balæna*, Linn. Only four or five species have been tolerably described, and even of these some are doubtful. Many others have been named, of the majority of which, however, the existence is as yet conjectural.

Order XI. Monotrema.

1. *Echidna*, Cuv. One species.
2. *Ornithorhynchus*, Blumenb. Two species.

The student will bear in mind that the preceding methodical abstract bears the date of 1827, and that several important additions, and a few corrections, have been made by various naturalists since that period. It presents, however, upon the whole, an accurate and ample view.[1]

General characteristics.

In the article Animal Kingdom of the present work,[2] we have endeavoured to sketch the general attributes and co-relations of the great primary divisions of the subjects of zoological science, and we shall not here repeat our statements. The class Mammalia on which we are now about to enter, stands at the head of that first great division of the animal kingdom, which, by reason of the brain and continuous lengthened mass of the nervous system being contained within the bony envelope of the cranium and vertebræ, is named the vertebrated division, and of course comprises all the higher classes, or *animalia vertebrata*. These are,—Mammalia, birds, reptiles, and fishes, the last of which alone, under the term Ichthyology, have as yet been illustrated in our present work.

The Mammalia in the system of Baron Cuvier, and indeed of all the other systematic writers (although Lamarck, guided by peculiar views regarding the *progressive* development of species, follows an inverse order), are placed at the head of the animal kingdom,—not only because they form the class to which we ourselves belong, but because they are endowed with the highest combination of faculties, the most delicate sensations, and the most varied movements. There certainly results from the totality of their physical qualities, an intelligence more perfect, and fertile in resources, less enslaved to the blind impulses of instinct, and consequently more capable of amelioration and improvement, than that of the other vertebrated tribes.

As their power or amount of respiration is moderate compared to that of birds, the great majority are formed for walking on the surface of the earth, or for certain motions dependent for support on bodies connected with that surface. The articulations of their bones have consequently precise forms which determine their movements, and even circumscribe them with rigour. Certain species, however, possess the power of raising themselves into the air by means of prolonged and extended membranes, with which their limbs are furnished; while others have those limbs so shortened and concealed beneath the teguments, as to render them incapable of progressive movement except in water; but, nevertheless, though fish-like in their forms, they in no way lose the characteristics of their class, and the unwieldy whale is as truly a warm-blooded mammiferous animal as the most active of monkeys.

In all Mammalia the upper jaw is fixed to the cranium, and the under one, composed of only two portions, articulates by means of a projecting condyle to a fixed temporal bone. The cervical vertebræ, as already mentioned, are seven in number. The anterior ribs are attached forwards by cartilaginous pieces to a sternum, formed of a certain number of vertical portions. The anterior extremities commence from a shoulder-blade, not articulated, but merely suspended in the flesh, and often supported on the sternum by an intermediate bone, named the clavicle. These extremities are further composed of an arm (*humerus*), a fore-arm (*radius* and *cubitus*[3]), and a hand,—the last named

---

[1] We do not here enter into the vexed question of the quinary or other circular systems of arrangement, as these are as yet somewhat too much connected with critical asperities, and have scarcely in themselves subsided into a lucid or tranquil element of science. We do not think our readers would have benefited by our adopting any of the so-called natural systems as the basis of the present article. We should not, however, hold ourselves excused were we not to advert with respect and gratitude to those who have, with various degrees of success, endeavoured to establish that system. In relation more particularly to our present subject, we had with some care prepared an abstract of Mr Swainson's views of the natural classification of Mammalia, but we now think that more justice will be done the enlightened author (and assuredly more advantage will accrue to the attentive reader) by his arrangement being taken rather in connection with the many interesting and valuable observations by which it is explained and supported, than in such disjoined and compendious form as would suit our present limits. It is indeed one of the disadvantages of such systems, that their merits cannot be fairly exhibited *linearly*, nor done justice to in any ordinary form of tabular exposition. We therefore earnestly advise the student to a very careful perusal of Mr Swainson's *Zoological Illustrations*, and of his papers, which he will find published in Dr Lardner's *Cyclopædia*. They ought to be in the hands (and heads) of every naturalist, and their unassuming form and moderate price fortunately render them accessible to all classes of the community.

[2] Vol. iii., p. 168.

[3] These two bones of the fore-arm are sometimes distinct, and capable of a certain oblique rotation on each other (as in man and monkeys); or they are fixed by their extremities (as among the majority of the *Feræ* and *Rodentia*). Sometimes the radius becomes the principal bone, and the cubitus, reduced to a rudimentary state, forms only a simple apophysis. This is the case among ruminating animals, and the genus *Equus* or horse tribe.

General characteristics.

being itself constituted by two ranges of small bones named *metacarpus*, and of fingers or *phalanges*. The extremities of these last bear the nails or hoofs. With the exception of the Cetacea, all the species have the first portion of the posterior extremities attached to the spine, and forming a girdle or pelvis, which in early age, is divisible into three pairs of bones, the *ilium*, which is attached to the spine; the *pubis*, which forms the anterior girdle; and the *ischium*, which forms the posterior. At the point of the union of these three bones is the cavity which contains the articulation of the thigh (or *femur*), to which is attached the leg, itself composed of two bones, the *tibia* or shin bone, and the *fibula*.[1] The leg is terminated by the foot, a compound organ, composed of parts analogous to those of the hand, and named the *tarsus*, the *metatarsus*, and the toes.

The head in the Mammalia is always articulated by two condyles on the atlas or first vertebral joint. The brain is always composed of two hemispheres united by a medullary lamina called the *corpus callosum*, containing two ventricles, and inclosing four pair of tubercles called the *corpora striata*, the *optic thalami*, the *nates*, and *testes*. Between the optic thalami there is a third ventricle, which communicates with a fourth placed beneath the cerebellum. The crura of the cerebellum always form beneath the medulla oblongata a transverse prominence called the *pons Varolii*.

The eye, lodged within its orbit, is protected by two eyelids, and the vestige of a third. Its crystalline humour is fixed by the ciliary processes, and the sclerotic coat is simply cellular.

In the ear of the Mammalia there always exists a cavity called the drum (*cavitas tympani*), which communicates with the *pharynx*, by means of a canal called the *eustachian tube*, and is closed externally by the *membrana tympani*. This cavity contains four small bones known as the *incus* or anvil, the *malleus* or hammer, the *stapes* or stirrup, and the *os orbiculare* or spheroid bone. The ear is further composed of the *vestibule*, at the entrance of which is placed the stapes, and which communicates with three semicircular canals, and of the volute or *cochlea*, which terminates by one of its scalæ in the tympanum, by the other in the vestibule.

The cranium may be said to be composed of three compartments:—the anterior formed by the two frontal bones and the ethmoid, the intermediate by the parietal bones, and the sphenoid, and the posterior by the occipital. Between the occipital bones, the parietals, and the sphenoid, are inserted the temporal bones, a portion of which belong, properly speaking, to the face. In the fœtal condition these bones exhibit various subdivisions, still more numerous in the embryo state, and become more and more compact and simple in the adult animal.

The face is formed essentially of the two maxillary bones, between which passes the nasal canal; these bones have in front the two intermaxillaries (which bear the incisive teeth), and behind them the two palatines, while between them descends the single lamina of the ethmoid named the *vomer*. On the openings of the nasal canal are the proper bones of the nose. The jugal or cheek bone unites on each side the maxillary to the temporal, and often to the frontal bone; and finally, the lachrymal occupies the internal angle of the orbit, and sometimes a part of the cheek.

The tongue is always fleshy, and attached to a bone called the hyoid, suspended by ligaments to the cranium.

The lungs, two in number, are subdivided into lobes composed of an infinity of little cells, and are always inclosed without adhesion in a cavity formed by the ribs and diaphragm, and lined by the pleura. The organ of the voice is always at the upper extremity of the tracheal artery or windpipe, and a fleshy prolongation called the *velum palati* or soft palate, establishes a direct communication between the larynx and back of the nostrils.[2]

General characteristics.

Dwelling habitually on the surface of the earth, mammiferous animals are less exposed than certain other classes to extreme alternations of heat and cold, their covering or hair is of moderate thickness, and is usually of a slighter texture in the species of warmer climes. Linnæus, the nature of whose genius led him to seek for the establishment of a kind of distinctive opposition in the characters of animals, maintained, among other generalised dicta, that Mammalia were furnished with hairs, birds with feathers, and fishes with scales. This is true in a general sense, although the Cetacea, which dwell exclusively in the water, are destitute of any hairy covering, and the pangolins and other species seem covered with scales. Blainville, indeed, is of opinion that the usual hairy coating exists, though under another aspect, equally among whales as in ordinary quadrupeds, and the distinction presented by the scaly species of land animals is more apparent than real. Yet as many birds are also partially covered by what does not essentially differ from hair, we do not think that the name of *Piliferes*, by which M. de Blainville desires to designate all mammiferous animals, is in any way preferable to that derived from their functions of maternity. Quadrupeds have usually two kinds of covering intermingled,—the hairy, which is of a more or less stiff or consistent texture (varying as it were from *silk* to *bristle*), and from its greater length is the more apparent and external,—and the woolly, which is extremely soft and fine, and is usually concealed beneath the other. The domestic races of the sheep, however, form a remarkable and highly beneficial exception to the contrary, in the great length and abundance of the woolly portion, and the almost total disappearance of the silken or hairy. There is also an approach to this character in most animals belonging to cold countries, while in those of tropical regions the silky coat becomes much developed, and the woolly diminishes or disappears. The quantity or proportional abundance of wool is usually in an inverse ratio, that of silk in a direct ratio, to the temperature. The silky coat or hair, is of great length on particular portions of several species, such as the mane of the lion and the horse, and the tail of the latter; and a species of Indian bear (*Ursus labiatus*) is remarkable for the length of its hair, which measures from seven to nine inches over the general surface, and on particular spots is nearly a foot long.

In some species the covering is partially or even entirely composed of spiny projections, varying in form and aspect; such as those of the hedgehog, tanrec, echimys, porcupine, and others. All these spines are usually pointed and cylindrical, and bear the form of a gigantic hair. But in the common porcupine (*Hystrix cristata*) the tail is garnished with cylindrical tunnels, which are open transversely at their extremity, thus resembling quills which have been cut across at the commencement of their opaque portion. In all the spiny species naturalists have remarked that there is a great development of those muscles which act upon the skin, a condition, in truth, indispensable in rendering the spines effective as weapons of defence.

The colours of mammiferous animals are in general much less brilliant than those of several other classes, and are almost entirely destitute of that metallic splendour

---

[1] These two last-named bones offer the same variations in their relation to each other, as do those of the fore-arm just noted.

[2] *Règne Animal*, t. i., pp. 60-63. For details of internal structure, the general reader is referred to the article COMPARATIVE ANATOMY of this Encyclopædia, vol. iii., p. 74; to the writings of Camper; or to the Sketch prefixed by M. Desmarest to his *Mammalogie*. The professional student will seek the more laboured systems of Cuvier, Meckel, De Blainville, Carus, or the excellent *Outlines* by Dr Grant, and the admirable Dissertations of Professor Owen.

General characteristics.

which so enriches the livery of the feathered tribes. In this particular the Chrysochlore, a small insectivorous animal from Africa, allied to the mole, forms almost the sole exception. Another general characteristic of the coat of the Mammalia consists in the colours being much paler over the lower surface than on the flanks or dorsal regions. This observation applies not only to the ordinary quadrupedal form, in which the under surface is less exposed to view, but to the kangaroos and other leaping kinds, in which from the almost vertical position of the body, the abdomen and the back are equally open to the influence of light and air. The exceptions are of two kinds, 1st, of animals like the polar bear, which are of one uniform colour throughout; and, 2dly, of certain other species like the glutton, ratel, and badger, which are lighter above than below. Of this one of the most remarkable examples is furnished by an Indian animal called Panda (*Ailurus refulgens*), which is of a beautiful cinnamon red colour above, with the abdomen of the deepest black.

The colours of quadrupeds are sometimes mottled or closely intermingled,—an effect produced by each hair being composed of rings of different hues, as in most of the squirrels; sometimes these colours are more broadly varied, or in stronger contrast, as among the larger spotted cats or feline animals; but in the majority of quadrupeds the colours of each species are rather uniform than varied, although the *Makis* and others exhibit some strongly contrasted markings. The sexual distinctions, as derived from the external covering, are much less remarkable than among the feathered tribes, the female being for the most part only somewhat less vivid than the male. Neither does the progressive advancement to age from adolescence manifest changes so singular and extensive as those of birds, although among several species, such as stags, lions, and others, the colours in early life are differently disposed from what they are in the adult condition. The young fawn is spotted with white, an aspect which is permanent in that species of deer called axis, while young lions are variously marked with dark brown or black, thus resembling the matured condition of many of their congeners. This remarkable relation between the colouring of *young* individuals of one species, and that of other species of the same genus in the *adult* state, is likewise observable in birds, but with this difference, that the early plumage, usually resembling that of the female, is always more dingy and obscure than that of the adult, whereas, as already hinted, the covering of the young Mammalia is frequently more elegantly varied than that of their parents. The varieties of colour among domesticated animals are too numerous to be here detailed, and indeed too familiar to require illustration. Even among unreclaimed species frequent varieties occur, and moles and many other animals are found of a white or cream-colour. These changes have been observed to be extremely uncommon among the cheiropterous species, or bats. The term *albinism* is applied to the condition of the white varieties, that of *melanism* to that of the black ones; the former being more frequent in cold countries, the latter in warm ones. But melanism is much rarer than albinism, and has hitherto been observed chiefly among feline animals, deer, and rats. The water-rat, commonly so called (*Arvicola amphibia*), frequently occurs exclusively of a black colour, over a whole district of country. It has not yet been demonstrated as a distinct species, though by some regarded as such.

Besides the diseased or accidental condition of albinism, several species, such as hares, ermines, and foxes, become annually white in northern countries, during the winter season. Black seems the colour most persistent in these animals throughout the year; thus the ermine always preserves the black extremity of the tail, and the points of the ears are at all times of that colour in the Alpine hare. The same fact is exemplified among birds of the ptarmigan tribe. It is difficult, however, to determine distinctly whether these and other analogous changes are the direct result of cold, as the immediate cause, or belong to some other chain of providential facts by which the well-being of these creatures is sedulously guarded amid those inclement countries in which they have been doomed to dwell. At least we know that among birds we have numerous species with plumage of the purest white inhabiting the most sultry of the tropical regions, while the ominous raven, with a covering as usual of the deepest black, is one of the few species which braves the intensity of a polar winter, and is seen, or rather heard, throughout that long-enduring night, croaking among the desolate cliffs, or gliding like the spirit of evil along the barren ice-bound shores.

General characteristics.

Although the subject has not been investigated in detail, we know in a general way that albinism is produced by debilitating causes, and results from the absence of the colouring matter of the skin; and if, on the other hand, it could be demonstrated that melanism is rather the result of fortifying causes, and of a superabundance of the colouring material, we should then more clearly perceive how it happens that all species, whatever may be their natural hue, are liable to exhibit one or other of the phenomena in question.

Prehension, or the seizing and handling of their food, or other substances, is executed among carnivorous and gnawing animals (Feræ and Rodentia) by means of the toes, which are usually very distinct, and terminated by nails or claws more or less pointed. In some species, such as the squirrels among the Rodentia, and the racoons among the carnivorous kinds, the food is held by a kind of pressure between the two anterior paws, and carried upwards to the mouth. The hand of man is a much admired instrument, and more perfect in its way, although of the same general structure, than that of monkeys and other quadrumana; which, however (with the exception of the genus *Ateles*), possess an advantage over us in the opposable nature of the great toe, by which they are rendered equally expert with either extremity. They are, in truth, as the name imports, four-handed, and are consequently the most accomplished of climbers, as we may easily conceive, by imagining with what activity, in spite of his comparatively heavy form, a sailor would ascend the shrouds, or reef the sails, if his feet were so constructed as to grasp as firmly as his hands.

The toes in quadrupeds never exceed five in number, and have never more than three articulations: there are sometimes only two articulations, and the number of toes frequently differs on the anterior and posterior extremities. These parts have furnished excellent characters for classification, when not assumed as the sole and exclusive basis of arrangement. Thus Klein, the Königsberg naturalist, divided animals into orders and sections according to the form and number of the toes, thereby bringing into juxtaposition many species entirely dissimilar to each other, and at the same time separating others between which there existed the strongest natural alliance; while Linnæus, with his wonted sagacity, deduced from the toes only generic characters, subordinate to the more important parts of the organization, and thereby rendered them available in systematic arrangement. In many species, especially the feline, the toes are furnished with sharp, curved, retractile talons, which become very formidable weapons of defence or attack. In man, and the different species of monkeys, they are possessed of great discrimination in the sense of touch, and a false or at least exaggerated view of the subject has led Helvetius and others to attach an extraordinary degree of importance to the *hand*, as the medium of intellectual superiority in the human race. In bats the anterior toes assume a singular form, become greatly extended, and having their interstices filled up by membranes, act in the capacity

General characteristics.

of wings; while in seals, walruses, and cetaceous animals, such as whales, they pass by different gradations into the form of fins.

The prehensile power of the Mammalia is not, however, confined to their feet and hands. Many of the American monkeys make use of their tails, both in locomotion and for the seizure of their food; and the kinkajou is said to insert the tip of that portion of its body into holes in which crustacea lie concealed, and which seizing upon and pertinaciously adhering to the intruding organ, are speedily dragged from their concealment and devoured. But the proboscis of the elephant, terminated by a strong opposable appendage, is one of the most perfect prehensile instruments to be found within the range of the animal kingdom. The same mode of seizure, but with a more restricted action, is practised by the great tribes of ruminating quadrupeds, which, using their limbs only as organs of support and locomotion, collect their food by means of the mouth alone, that is, by a combined action of the lips, teeth, and tongue.

We need scarcely observe, that all mammiferous animals are viviparous, that is, produce their young alive, and, consequently, as their name implies, nourish them by means of the secretion named milk. This brings us round to the definition with which we started, and we shall now proceed to a short exposition of the orders of the class Mammalia, as established and defined by Baron Cuvier.

The variable characters which establish the most essential differences among mammiferous animals are derived from the organs of touch, on which depend their greater or less degree of ability and address, and from the organs of manducation, which determine the nature of their aliments, and regulate not only all that relates to the digestive functions, but also a cloud of other characteristics intimately connected with their habitual instincts. The perfection of the organs of touch may usually be estimated according to the number and mobility of the toes (using the word in its more enlarged acceptation as including the terminal portions of both the fore and hind extremities), and the mode and degree in which these parts are enveloped within the claws or hoofs. A hoof which entirely encompasses all that portion of the toes which touches the ground, of course not only blunts its feeling, but renders it incapable of grasping. The opposite extreme consists in a simple flattened nail, which covers only a limited terminal portion of the toes, and leaves the remainder in a state of delicate perception.

The habit of life in regard to food or regimen may be accurately inferred from the cheek-teeth, with the form of which the articulation of the jaws is always found to correspond. For the purpose of cutting flesh, these cheek-teeth (commonly called grinders in the herbivorous animals) are in the carnivorous kinds trenchant like a saw or scissars, and the jaws are so restricted in their movements as to be incapable of lateral or horizontal motion, and meet each other vertically, with a firm but circumscribed action. On the other hand, animals destined to live by the mastication of grain or herbs have flat-crowned cheek-teeth, placed in jaws capable of horizontal motion; and as it is desirable that the upper surface of such teeth should preserve a certain inequality, like that of a mill-stone, they are found to be composed of portions of unequal hardness, one of which wears quicker than the other. All hoofed animals are of necessity herbivorous, and provided with flat-crowned grinders, because their feet are incapable of seizing a living prey. But unguiculated animals exhibit a greater variety of form and diet, and differ greatly among themselves, not only in the structure of their teeth, but also in the mobility and perceptive powers of their toes. One special character in this respect, which has prodigious influence on the general address of animals, by multiplying their means of prehensile action. is the faculty before alluded to of opposing the thumb to the other fingers, so as to constitute a hand fitted for the secure and delicate seizure of the smallest objects. These various combinations, which in truth determine with great rigour the nature of the mammiferous tribes, have occasioned the establishment of the following orders:—

Characters of the Orders.

Among the unguiculated animals, commonly so called, the first is man, a privileged being, who enjoys a multiplicity of advantages over all other sublunary creatures, but who, in the technical language of zoology, is characterized by his erect position, and the possession of hands to his anterior extremities only. These, of course, are the accidents, not the essentials of his nature, and are inadequate to the description of a being who bears within him the germ of an immortal life. It is indeed the usual practice of naturalists to begin their systematic exposition of the animal kingdom with a "Nosce teipsum," followed by a sketch of the physical attributes of the human race, as if that race were undistinguished by a lofty and spiritual existence, by an independent and superior perception, entirely different in its essence and action from the nature of the external senses. We have previously reclaimed against this preposterous classification of Man, of him who was created "but a little lower than the angels," with the brutes that perish, and we shall not here depart from our accustomed rule, further than to mention that in Baron Cuvier's system, by which in other points we shall be mainly guided, the human race is regarded as the first order, and is named BIMANA, from the peculiarity above alluded to.

The next order (and it is that with which we shall commence our systematic exposition), is distinguished by what are regarded as hands on both the fore and hind extremities, and is hence named QUADRUMANA.

Then follows a great group which possess no free or opposable thumb on either the fore or hind extremities: these are the carnivorous animals, or order FERÆ.

In all the preceding orders we find three different kinds of teeth, viz. the molar or grinding-teeth, which are better named cheek-teeth, seeing that their function in carnivorous animals is rather to cut than to grind; the canine teeth; and the incisive teeth.

The groups which compose Cuvier's fourth order do not differ essentially in the nature of their extremities from the ferine order, but they want the canine teeth, and have incisives in front of the mouth, so disposed as to fit them admirably for that kind of manducation called gnawing. Hence they constitute the *Rongeurs* of the French naturalists—the order GLIRES or RODENTIA.

Following these we have certain kinds of which the toes are straitened and sunk within great claws, usually curved, and which moreover want the incisive teeth. In some even the canine teeth are absent, while a few are entirely deprived of those organs. They are all comprehended under the order EDENTATA.

The preceding orders are all unguiculated, that is, provided with nailed toes, capable of distinct and articulate movement. These, though still existent, become constrained and encrusted within a callous skin in the ensuing order, and decrease in number till in the solipedal family, corresponding to the genus *Equus* of Linn. (the horse tribe), there is only one apparent toe, covered by a single undivided hoof, on each foot. These groups constitute the order PACHYDERMA, so named from the usual thickness of their skins.

The other hoofed genera compose a very distinct group, distinguished by their cloven feet, the absence of true incisives in the upper jaw, and their quadruple stomachs. From certain peculiar functions of the last named organs they are named ruminating animals.—order PECORA.

Finally, there are several aquatic Mammalia, of which the posterior extremities assume the form and functions of a tail, while the anterior members act as fins. These are the gigantic whales and rolling porpoises, which, with others not necessary to be here named, constitute the great concluding order called CETACEA.

Probably the most objectionable part of the preceding system consists in placing all the pouched or marsupial animals (kangaroos, &c.) as the terminal portion of the carnivorous order. These creatures consist, in truth, of various groups, possessed of few characters in common, and ought no doubt to be distributed through several different orders, instead of being brought together (merely in consequence of each being characterized by the possession of a *marsupium* or pouch) as a ferine family, under the name of *Marsupialia*. Their creation into a distinct order, as by some proposed, is for the same reasons equally objectionable.

Although in the present treatise we follow the system of Baron Cuvier's "Règne Animal," rather than that of any more modern, or, it may be, amended classification, we shall yet be careful to introduce from time to time such observations of contemporary naturalists as may seem to us to be in any way truly corrective of that system. We think, indeed, that there may possibly be some misconception on the part of many modern writers, who, deriving almost all of what they essentially know from the labours of the great French anatomist, and obviously and almost confessedly hanging their own restricted and superficial observations on the gigantic trunk which he had already raised (and which centuries will fail to undermine), suppose that because a few glittering leaves or even "bright consummate flowers" of their own imagining may sometimes meet the view, that they have *created a system!* Now, the actual truth may rather be, that had not the system itself been previously prepared for them, and so much transparent light called forth from such a depth of darkness, they might as easily have found their way in absence of the sun through tangled woods or pathless deserts, as have by actual observation or any intellectual effort of their own, ascertained the existence of a single great principle in natural history. But be this as it may; we have already presented the reader with tabular views of the prevailing modern systems, and these he may study and compare together, and with that which follows, and draw his own conclusions. This process will assuredly be to his, if not to their advantage.

ORDER I.—QUADRUMANA.

QUADRUMANOUS, OR FOUR-HANDED ANIMALS.

Teeth of three sorts—incisive, canine, and molar. Each of the four extremities furnished with a thumb, free in its movements, and capable of being opposed to the other fingers or toes, which are long and flexible, and bear a strong resemblance to the fingers of the human hand. The eyes are directed forwards. The mammæ, which are pectoral, vary in number from two to four. A bony partition separates the temporal cavities from the orbits; but the nasal bone does not exhibit the suture observable in that of man. The stomach is simple and membranous, and the intestines are short, and greatly resemble those of the human race.

The animals of this varied and extensive order, familiarly known under the names of orang, ape, monkey, &c. inhabit the warmer regions of Asia, Africa, and America. A single species remains as a European representative on the rock of Gibraltar, either by descent as an indigenous animal, or by accidental importation from the opposing coast of Barbary, where it is extremely frequent. The quadrumanous order dwells almost exclusively in woods, feeding in general on fruits, roots, grain, and other vegetable produce. A passage, however, occurs in Ogilby's Translation of Niewhoff's China, which, probably more remarkable for graphic effect than accuracy, assigns a very different disposition to some large species of the order. "The province of Fokien hath an animal perfectly resembling man, but longer armed, and hairy all over, called *Fese*, most swift and greedy after human flesh; which, that he may the better take his prey, *he feigneth a laughter*, and suddenly, while the person stands listening, seizeth upon him."[1] The propensity of several of the smaller species to feed on eggs and insects is better ascertained.

The most remarkable characteristic of their external form is the extraordinary resemblance which many of them bear to the human race; and their internal structure offers equally striking analogies. Their distinctive character, however, is by no means difficult to seize;—their posterior extremities, naturally unfit for the assumption of an erect position, are admirably adapted for prehension, and the species are consequently the most active in their *arboreal* habits of all the larger animals. The opposable thumb on all the four extremities, although a leading character in the great majority of the order, and the one from which the ordinal name is itself derived, cannot strictly be said to occur in all the genera. In truth, it is ever thus with any *single* character, however influential, which naturalists may choose to select as the basis of any great natural group. A combination with other features is usually required, otherwise the organ selected will be found to undergo so many modifications, as not seldom to evade or contradict the definition. Thus in the monkey tribe the genera *Ateles* and *Colobus* want the thumb to the anterior hands, and in several of the *Semnopitheci* it is merely rudimentary. These therefore can scarcely be called *quadrumanous*, if we take the term in its strictest etymological acceptation. It has been remarked as a fact worthy of attention, that the anomalies by which many quadrumanous animals depart, as it were, from their characteristic type of form, affect the anterior rather than the posterior members. In man, the anterior extremities alone have a free and opposable thumb. Among the Quadrumana, on the contrary, the so called thumb exists constantly on the posterior members, in a well developed state, but is frequently absent or rudimentary on the anterior extremities. Even among marsupial species we frequently find a free thumb on the hind feet, but never on the anterior, and the like structure is observable in a peculiar animal, usually ranged near the squirrels, the *Cheiromys Madagascariensis*. Thus it appears that various animals possess a true, that is, opposable thumb, on the hind feet, which do not possess it on the fore ones, and that the inverse character occurs only in a single creature, of which the reader and writer of the present article afford examples.

The quadrumanous order of animals certainly holds a high rank in the animal kingdom; but, though apes and monkeys often astonish us by their apparent power of imitating the actions of men, we agree with Buffon in thinking that they are not in a corresponding degree superior to other brute animals which do not possess that power. The talent, in fact, does exist in many species, but is necessarily (from their structure) confined to the imitation of their own kind; but the ape, though he does not belong to the human race, copies many of our actions (and unavoidably) through the resemblance of his organization. Thus what most have ascribed to superior intelligence, is nothing but the result of a gross affinity of form and figure.

In accordance with the modern arrangements, our pre-

---

[1] Second edition, p. 413.

Quadrumana.

sent order is divisible into two extensive families, the Simiadæ and Lemuridæ, groups corresponding in a great measure to the old genera *Simia* and *Lemur* of Linn.

FAMILY I.—SIMIADÆ, Apes in general.

These, in their ordinary form and aspect, more or less resemble man. They have four straight incisive teeth in each jaw, and all their nails are flat. Their molar or cheek teeth, like those of man, are bluntly tuberculated, and in their habits of life they are essentially frugivorous, although their appetites, like our own, seem very accommodating. Their canine teeth, however, exceed the others in length, and often require for their points a corresponding lodgement in the opposing jaw. The family is further divisible into two minor groups.

1st Sub-Family.—Simiæ Catarrhini, or Apes of the Old World.

Of these the cutting or incisive teeth are $\frac{4}{4}$, the canine $\frac{1-1}{1-1}$, the cheek teeth or grinders $\frac{5-5}{5-5}$; total 32. The nostrils, as the name implies, are separated only by a narrow membrane. The tail, frequently wanting, is never prehensile.

Genus Troglodytes, Geoffroy. *Pithecus*, Cuv. Canine teeth very slightly elongated, and placed close to the incisors and molars, as in man; head rounded; muzzle short; facial angle, 50°;[1] superciliary ridges strongly marked; no cheek pouches, tail, or callosities; no apparent intermaxillary bone; ears resembling those of man, but large and projecting; arms of moderate length.

The only known species of this genus is the Chimpanzee, or black orang of Africa (*Simia troglodytes*, Linn.), the *Troglodytes niger* of the modern system.[2] (See Plate I. of this vol., figure 2.) The colour of the fur is brownish black. The form of the body and limbs more nearly approaches the human than that of any other animal. The head is middle-sized, somewhat flattened in the crown, and scarcely rising above the level of the superciliary ridges. The chest is broad, the arms robust, and the anterior thumb is placed lower on the wrist, and seems more serviceable than that of the Asiatic species.

Although we feel desirous to render the present treatise not only useful to the scientific student, but in some measure interesting to the general reader, by the occasional introduction of what is called *popular* matter, we would rather at present hold ourselves excused from the repetition of the various anecdotes which might be brought forward without much effort, to illustrate the history of this and the other orang.[3] Many of these are apocryphal, and, though amusing, tend to mislead rather than instruct. Two species of African orang-outang seem to have been described by ancient writers, but as from all later researches we cannot infer the existence of more than the one above indicated, it is probable that the mistake originated from the young and old of the same species having been seen apart at different times. "The greatest of these two monsters," says Battell, "is called *Pongo*, and the less *Engeco*. This Pongo is exactly proportioned like a man; but he is more like a giant in stature, for he is very tall, and hath a man's face, hollow-eyed, with long hair upon his brows. His face and ears are without hair, and his hands also. His body is full of hair, but not very thick, and it is of a dunnish colour. He differeth not from a man but in his legs, for they have no calf. He goeth alway upon his legs, and carrieth his hands clasped on the nape of his neck when he goeth upon the ground. They sleep in the trees, and build shelters from the rain. They feed upon fruits that they find in the woods, and upon nuts; for they eat no kind of flesh. They cannot speak, and appear to have no more understanding than a beast. The people in the country, when they travel in the woods, make fires where they sleep in the night; and in the morning, when they are gone, the pongos will come and sit about the fire till it goeth out; for they have no understanding to lay the wood together, or any means to light it. They go many together, and often kill the negroes that travel in the woods. Many times they fall upon the elephants which come to feed where they be, and so beat them with their clubbed fists, and with pieces of wood, that they will run roaring away from them. Those pongos are seldom or never taken alive, because they are so strong that ten men cannot hold one of them; but yet they take many of their young ones with poisoned arrows. The young pongo hangeth on his mother's belly, with his hands fast clasped about her, so that when the country people kill any of the females, they take the one which hangeth fast upon its mother, and, being thus domesticated and trained up from their infant state, become extremely familiar and tame, and are found useful in many employments about the house."

Purchas states, on the authority of a personal conversation with Battell, that an African orang once carried off a young negro, who lived during an entire season in the society of these animals, and on his return reported that they had never injured him, but, on the contrary, seemed greatly delighted with his company; and that the females especially (this was natural) shewed a great predilection for him, and not only brought him great abundance of nuts and wild fruits, but carefully and courageously defended him from the attacks of serpents and beasts of prey. According to Pyrard, the great Ape of Sierra Leone called *Barris* (undoubtedly the adult black orang) is so remarkable both for strength and industry, that when properly fed and instructed, it serves as a very useful domestic. It usually walks upright (so it is alleged, we doubt not most erroneously), will pound any thing in a mortar, or fetch water from the river in a little pitcher, which, however, must be immediately taken from it on its return, else it will allow it to tumble to the ground. Passing by the impostures of Gamelli Careri, it may be asserted that the equally amusing, and scarcely more authentic, narrations which Buffon and others have compiled from the writings of Father Jarrie, Guat, and Froger must be consulted with critical caution by whoever seeks to ascertain the actual history of this extraordinary creature. With the exception of such information as has been drawn from the observance of one or two young individuals sent alive to Europe, our knowledge of its nature has in no way increased. Naturalists have become aware of the inaccuracy and exaggeration of previous portraitures, but have not themselves succeeded in the completion of the picture. It is indeed most singular that when the history of animals inhabiting New Holland, or the most distant islands of the Indian Ocean, are annually receiving some new or corrected illustration, the most remarkable species of the brute creation, inhabiting a comparatively neighbouring country, should have remained for about two thousand years under the uncertain shadow of an almost fabulous name. The African orang appears to be a gregarious animal, an inhabitant of the forests, of an intelligent disposition, and capable of a considerable degree of education, though probably fierce and irreclaimable in the adult state. It is believed that the full grown animal has never yet been examined by any naturalist. In that uncouth condition it is probably the "great wild man of the woods," of whose existence we do not doubt, but of which (setting aside the obviously fabulous narrations) only vague indications have been given by some African travellers.

---

[1] In accordance with the usual custom of naturalists, we here occasionally indicate the facial angle, although we are satisfied that that character admits of too wide a range of variation to be relied upon as a *specific* indication. An examination of an extensive series of skulls in the Museum of the College of Surgeons (Edinburgh), had long ago convinced us that remarkable changes take place in the form and proportions of the cranium in the same species, according to the age of different individuals. For example, in the dog, badger, common pig, and especially in the *Sus Babyroussa*, these differences are very remarkable.

[2] *Homo sylvestris*, Tyson; *Man of the Woods*, Edwards; *Great Ape*, Pennant; *Jocko*, Buffon; *Pongo* of Audebert, and of the Supplement to Buff. tom. 7; but quite distinct from the Pongo of Wurmb. This animal was dissected by Professor Traill, who discovered in it a motor muscle of the thigh that had escaped the notice of Tyson, Camper, and Cuvier. (*Wern. Trans.* vol. iii.)

[3] We beg to refer the curious to a very accessible little work, "The Natural History of Monkeys," which forms a volume of Sir William Jardine's interesting and economical *Naturalist's Library*. A book entitled *Anecdotes of Monkeys* was previously before the public.

Of the natural dimensions of the black orang, we can say nothing. The young brought to Europe have seldom much exceeded two feet in height. It is native to no other country than Africa, but we are as yet unacquainted with the extent of territory which it occupies in that continent. Angola, the banks of the river Congo, and all the districts which border the gulf of Guinea, are the localities in which it has as yet most frequently occurred.

GENUS PITHECUS, Cuv. Geoff. Canine teeth somewhat exceeding the others in length, but not separated from them by any interspace, and slightly crossing each other at their points; molar teeth more square than those of man, and more strongly tuberculated; head rounded; facial angle 65 degrees; no superciliary ridges;[1] no cheek pouches, tail, or callosities; sutures of the intermaxillary bone apparent; ears rounded, resembling those of man, and applied close to the sides of the head; arms very long.

This genus likewise consists of only one clearly ascertained species, commonly called the red or Asiatic orang-outang (*Simia satyrus*, Linn.), the *Pithecus satyrus* of the modern systems.[2] (See Plate I., figure 1.) Like the preceding it is not distinctly known in the adult state. The specimen described by Dr Clarke Abel,[3] was brought from Banjarmassing on the south coast of Borneo. Its height, or rather length, from the heel to the crown of the head was two feet seven inches. The hair was of a brownish red colour, and covered the back, arms, legs, and outside of the hands and feet. On the back it was in some places six inches long, and five upon the arms, but very short and thinly scattered on the back of the hands and feet. It was directed downwards on the back, upper arms and legs, but upwards on the fore-arms. The face had no hair except on the sides, somewhat in the manner of whiskers, and a very thin beard. The palms of the hands and feet were quite naked. The arms were long in proportion to the height of the animal, their span measuring full four feet seven inches and a half. The legs were short compared with the arms. The hands were long compared with their width, and with the human hand. The fingers were small and tapering, the thumb very short, scarcely reaching to the first joint of the fore-finger. All the fingers had perfect nails of a blackish colour, and oval form, and terminating exactly with the extremities of the fingers. The feet were long, and as usual resembled hands in the palms and finger-formed toes, but they were likewise provided with good heels. The great toes were very short, attached at right angles to the feet close to the heel, and were entirely without nails.

This animal was utterly incapable of walking in a perfectly erect position, and never wilfully attempted so to do. His progressive motion on a flat surface was accomplished by placing his bent fists upon the ground, and drawing his body between his arms, moving in the manner of a decrepit person supported on stilts. It is thus probable that in a state of nature he scarcely travels on the ground at all, his whole external form and structure proving his fitness for climbing trees and clinging to their branches. While in Java, he lodged in a large tamarind tree near Dr Abel's dwelling, and formed a bed by intertwining the smaller branches and covering them with leaves. He exhibited few of the grimaces of the monkey tribe, and was in no way prone to mischief. His aspect was grave, mild, almost melancholy. His chief amusement consisted in swinging himself from bough to bough; and, when on board of ship, he made use of the various tackling for the same purpose. On only two occasions was he seen violently agitated. When the vessel in which he sailed was off the island of Ascension, eight large turtle were brought on board, when he instantly mounted to a higher part of the ship than he had ever reached before, and, looking down upon the reptiles, projected his long lips into the form of a hog's snout, uttering at the same time a most peculiar cry. He enacted the same part on another occasion, on seeing some men in a state of nature splashing in the sea. Perhaps he took them for Mr Swainson's desired natatorial type of the quadrumanous order. We regret to add, that he died in the course of his second year's residence in this country. Our climate, in spite of coal fires and pipes of steam, is too cold, moist, and variable for these dwellers in the tropic woods, and a complaint analogous to consumption speedily puts a period to their shivering existence.

It is the opinion of Baron Cuvier,[4] that an obscurely known and almost gigantic animal, described by Wurmb[5] under the name of the Pongo of Borneo, ought to be regarded as the adult condition of the Asiatic orang-outang. The reasons assigned for this alleged identity, so far as we can collect them, from a notice on the subject by M. de Blainville,[6] are chiefly these:—As no orang-outang has ever been seen in Europe, or described by any European naturalist which exceeded the age of two or at most three years, it has consequently never been observed at all in the adult state. Observation has demonstrated, that the muzzles of apes in the menagerie of the Jardin du Roi prolong considerably with age; and it is known that the facial angle, both in men and monkeys, decreases as the individuals advance in years. The compression of the cranium has also been observed to take place from natural causes in after life. In the year 1818, Baron Cuvier received from India the head of an orang-outang, which resembled the ordinary species (the red orang) in most respects, but was remarkable for the prolongation of the muzzle, and the development of the superciliary ridges. Its characters were, in short, intermediate between those of the Asiatic orang-outang and the pongo of Borneo, from which it is concluded, that the former, in the state in which we have hitherto known it, is the young of the latter, the specimen adduced by Cuvier being regarded as an adult example of the same species, which had not, however, attained the maximum of its development. That the skeleton of the pongo in the Paris Museum was of great age, is proved by the general condition of its ossification, the state of its teeth, and the great development of the osseous crests of the cranium; the same characters being observed in old baboons, the young of which, without exhibiting so marked a disparity as that which exists between the red orang-outang and the pongo, nevertheless differ greatly from their parents. Lastly, the relative dimensions of the red orang-outang, of the intermediate specimen described by Cuvier, and of the adult pongo, are graduated in exact proportion to the development of the characters drawn from the crests of the cranium, and the prolongation of the facial bones.

---

[1] This character, we doubt not, applies only to the young animal. The ridges will probably be found strongly developed in the adult.

[5] *Mem. de la Soc. de Batav.*, t. 2, p. 245.

[6] *Note Sur l'Orang-outang, Jour. de Phys.* t. 1, p. 311.

The preceding observations, if not conclusive, are at least logical. But we cannot help bearing in mind that Sir Stamford Raffles,[1] in mentioning the occurrence of the orang-outang in Sumatra, states that it is there called by the natives orang *Pandak*, or the pigmy. Now, vernacular names are generally bestowed with some perception of natural character and attributes, and it is by no means usual for a people, however unobservant, to bestow, as the general appellation of a species, a title which applies to it only in a state of youthful imbecility; and if the creature in question attained in its adult state to the enormous stature of the pongo or great orang, we conceive it could scarcely do so without being occasionally observed of such a size as to render the name of pandak inapplicable. Nor do we see for what reason the great pongo, an animal of the most wary disposition, and of such extreme rarity, that not more than two or three examples of its occurrence are yet known to naturalists, should bring up its offspring so frequently within the range of human visitation. That it should be itself all the while unknown and invisible within the circle of its own domestic haunts (admitting it to be the parent of the red orang), is a circumstance still more difficult of explanation.

Whether these species, then, are identical or otherwise, is certainly still an undecided point. Another of equal interest and importance regards the specific nature of that gigantic animal killed some years ago on the north coast of Sumatra by Captain Cornfoot or his crew, and likewise described by Dr Clarke Abel.[2] It was upwards of seven feet in height when placed in a standing posture, and measured eight feet when suspended by the neck for the purpose of being skinned. On the spot where he was killed there were several tall trees, which greatly prolonged the attack; for such was his strength and agility, that his pursuers were unable to take a determinate aim, until they had felled all the trees but one. He received numerous balls before he was brought down, and then he lay upon the ground, as dead, exhausted by many wounds, with his head resting on his folded arm. It was at this time that an officer attempted to give him the coup de grace, by thrusting a spear through his body, but he instantly sprang upon his feet, wrested the weapon from his antagonist, and shivered it in pieces. This was his last effort, yet he lived some time afterwards, and drank, it is said, great quantities of water. He appeared to have travelled from some distance to the place of this "untoward event," for his legs were caked with mud up to the knees. On the reception of each deadly wound, he placed his hand over the injured portion, and distressed even his relentless pursuers by the human-like agony of his countenance. Indeed, his piteous actions, and great tenacity of life, are said to have rendered the scene altogether highly affecting. At the same time, it seems odd that so much sentimental perception should have been vouchsafed to those who committed the onslaught, and who were under no absolute necessity of bringing the business to so tragical a close.[3]

Genus Hylobates, Illiger. Muzzle short. Canine teeth lengthened. Facial angle 60 degrees. No tail nor cheek pouches. The posteriors furnished with callosities. Arms extremely long.

This genus contains the species commonly called Gibbons or long-armed apes, none of which are as yet known to attain the formidable dimensions of the great orangs. In their habits they are gregarious, and extremely shy in a state of nature, although their haunts are often betrayed by their singular howlings. In aid of these peculiar cries some of the species possess guttural sacks, resembling those of the howling monkeys of South America. Their distribution is confined to India and the Asiatic islands, where, like all their congeners, they inhabit forests, from which they seldom stray, and out of which they are easily captured, from the extreme awkwardness and difficulty with which they advance on *terra firma*, owing to the disproportionate length of their fore-arms.

Of the species, which are numerous, the most ancient, if not the best known, is the common gibbon, *Hylobates Lar* (*Simia Lar*, Linn.). The fur is entirely black, the face surrounded by grey hairs, the nose flat, and the ears not unlike the human. The disposition of this animal is mild and gentle. In a state of domestication, it receives its food without manifesting any greedy impatience, and exhibits a strong attachment to those with whom it has become acquainted. It is a native of the coast of Coromandel, and occurs also in the Peninsula of Malacca and the Molucca islands. It was probably one of this species which Father le Compte had an opportunity of examining, and which he says walked on two feet, and had "a face like a Hottentot." The white-handed gibbon from Sumatra, formerly regarded as a variety of the preceding, is now described as distinct, under the specific name of *albimana*.[4] We have, moreover, the little gibbon, *H. variegatus*, from Malacca, the active gibbon, *H. agilis*, from Sumatra, Harlan's gibbon, *H. Hoolock*, from the Garrow Hills, the Moloch gibbon, *H. leuciscus*,[5] from Malacca and the isles of Sunda, and the Siamang, *H. syndactyla*, from Sumatra. The last named, which we owe to the valuable researches of Sir T. S. Raffles, is distinguished by this peculiarity (from which it derives its specific name), that the first and second fingers of the hinder hands are united together as far as the middle of the second phalanx. It is entirely black, the face without hair, and the canine teeth long. It usually occurs in large troops, conducted, it is said, by a chief, whom the Malays believe to be invulnerable. Let them try a rifle. These assemblages remain quiet during the day, but at sunrise and in the evening twilight, they cause the forests to resound with the most dreadful cries, sufficient to deprive an unaccustomed traveller of his senses.

Genus Cercopithecus, Erxleben. Cuv. Desm. Canine teeth projecting, with interdentary spaces for their reception when the jaws are closed. Posterior molars with only four tubercles. Head rounded. Muzzle moderately projecting. Facial angle various. Ears of medium size, sometimes rounded, sometimes slightly angular above and posteriorly. Hinder limbs greatly developed. Cheek pouches and callosities. A long tail, not prehensile.

This great generic group is composed of animals named *Guenons* by the French naturalists, and is by far the most numerous and varied of the monkey tribes. It is almost exclusively African in the localities of the species. These live in troops, and commit great devastation in gardens and cultivated fields. They are easily tamed. The genus has been greatly subdivided in recent times, but we cannot here enter into any detailed exposition of the minor groups. We shall briefly describe and characterise a few of the principal species.

[3] We have figured the hands and feet of this extraordinary orang, of the size of life (from beautiful models transmitted to the Royal Society of Edinburgh from Calcutta, by George Swinton, Esq.). See Wilson's *Illustrations of Zoology*, vol. i. plates 33, and 34.

[4] *Zoological Jour.*, No. xiii. p. 107.

[5] This is the Wou-wou of Camper, but not the species so named by Fred. Cuvier, which is the true *H. agilis*. Wou-wou seems to be a native name of some extent of application, and therefore not specifically distinctive.

The golden guenon (*Cerc. auratus*, Geoff. Ann. Mus., t. 19, 93) has the fur of a golden-yellow colour, and of considerable length upon the ears, cheeks, and forehead. There is a black spot upon the knee. Native of the Moluccas.

The Talapoin monkey of Shaw and Pennant (*Cerc. talapoin*, Geoff. ibid.), is a doubtful species, by some regarded as the young of the Malbrouk. Its locality is uncertain.

The varied monkey of English authors (*Cerc. mona*, Geof. ibid. p. 95) is distinguished by its flesh-coloured lips and nose. The upper part of the head is a brilliant golden-green; the back and sides of a lively chesnut colour, speckled with black; the upper parts of the legs, thighs, and tail are of deep slaty grey, passing into black; and there are two white spots on each buttock. This is an African species, regarded by Buffon as the *Kebos* of the ancients. It is remarkable for its graceful motion, its elegance of form, and gentle docility of disposition.

The red monkey (*Cerc. ruber*, Geoff. ibid. p. 96), has the face flesh-coloured, the ears black; a black band passing over the eyebrows, and two black lines above the lips, give the appearance of moustachios. The upper parts of the face are of a bright reddish fawn colour, passing beneath into ash colour. From Senegal.

The Palatine monkey (*Cerc. Diana*, Geoff. ibid.), is of a deep chesnut colour on the back, with grey flanks, a pale oblique line upon the thighs, the chin and throat white, and a white crescent on the forehead,—from whence the mythological specific name. Congo and the coast of Guinea.

GENUS CERCOCEBUS, Geoff. Teeth as in preceding genus. Muzzle rather long. Head triangular. Facial angle about 45 degrees. Superior margin of the orbits paired, and notched interiorly. Nose flat and high. Anterior hands with slender thumbs, approximate to the fingers; posterior hands with broader thumbs, placed more apart. Callosities strongly developed. Tail longer than the body.

Here we place the Callithrix or green monkey (*Cerc. sabæus*), a well-known species from the African coasts and the Cape de Verd Islands, frequently imported alive into this country. Its colour is greenish-yellow above, somewhat grizzled on the sides of the body and outsides of the limbs, which become gradually darker towards the hands. The face, ears, and hairless portions of the hands are quite black. The neck and chest are white; the under parts have a tinge of yellow, and the insides of the limbs are grey. An account of the shooting of this species is given by M. Adanson. "But what struck me most, was the shooting of monkeys, which I enjoyed within six leagues this side of Podor, on the lands to the south of Donai, otherwise called Coq; and I do not think there ever was better sport. The vessel being obliged to stay there one morning, I went on shore, to divert myself with my gun. The place was very woody, and full of green monkeys, which I did not perceive but by their breaking the boughs on the tops of the trees, from whence they tumbled down upon me; for in other respects they were so silent and nimble in their tricks, that it would have been difficult to hear them. Here I stopped, and killed two or three of them, before the others seemed to be much frightened; however, when they found themselves wounded, they began to look for shelter, some by hiding themselves among the large boughs, others by coming down upon the ground; others, in fine, and these were the greatest number, by jumping from one tree to another. Nothing could be more entertaining, when several of them jumped together on the same bough, than to see it bend under them, and the hithermost to drop down to the ground, while the rest got further on, and others were still suspended in the air. As this game was going on, I continued still to shoot at them; and though I killed no less than three-and-twenty in less than an hour, and within the space of twenty fathoms, yet not one of them screeched the whole time, notwithstanding that they united in companies, knit their brows, gnashed their teeth, and seemed as if they intended to attack me."[1]

Another well-known species is the Malbrouc of Buffon, the dog-tailed baboon of Shaw (*Cerc. cynosurus*, Geoff.). It is of an olive-brown above, whitish beneath, with a pale band above the eyes. This species is one of the largest of the guenon group, measuring about a foot and a half from muzzle to tail. It possesses remarkable dexterity in the use of its hands, and although when aloft it is one of the most agile of all the wood-haunting animals, its motions on the ground are extremely awkward from the disproportionate length of the hinder limbs. We find, accordingly, that the malbroucs rarely descend to the earth. "Assembled in troops, they dwell for the most part in those capacious canopies of verdant foliage which cover the rich forests of Southern Asia, fellow-citizens with the birds, exposed to no danger but from the larger of the serpent tribe, or the more insatiable rapacity of man. In these lofty retreats they are found in such numbers, as to annoy the traveller, as well by the petulance of their motions, as the incessant iteration of their cries."[2] The Malbrouc in confinement is an unsociable creature, being either petulant and irritable, or morose and melancholy. He is mischievous when indulged, and sulky when kept in order. He inhabits Bengal. Numerous other species pertain to the generic group named *Cercocebus*.

GENUS SEMNOPITHECUS, F. Cuv. Canine teeth much longer than the incisors. The posterior molars of the lower jaw with a fifth tubercle. Tail and members long in proportion to the size of the body. Anterior thumb very short. Muzzle not greatly projecting. Cheek pouches and callosities.

The negro monkey of Pennant (*Sem. Maurus*, Geoff.) is entirely of a black colour, with the exception of a white spot beneath, at the base of the tail. It is said to be of a fawn colour when growing, and inhabits the island of Java. The only other species we shall mention of our present subdivision, is the Entellus Monkey of M. Dufresne (*Sem. Entellus*, Cuv.), which is of a pale yellowish-grey colour, with black hair on the eyebrows and sides of the head, directed forwards. Although systematically described only during recent years, it has long been well known in Bengal, and is one of the species venerated in the religion of the Brahmins. Its motions are slower than those of most monkeys, and the expression of its countenance betokens unalterable apathy. The height of the specimen in the London Zoological gardens exceeded two feet when in a sitting posture. The tail, which was rarely unfurled, measured nearly three feet. According to Mr Bennet, it is identical with the Ceylonese species described by Thunberg and Wolf. It is said to be frequently found in a domestic state in Ceylon, and is held in such respect by the natives, that whatever ravages it may commit, the latter dare not venture to destroy it, but merely frighten it away by cries, if possible, more discordant than its own. "Emboldened by this impunity, these monkeys come down from the woods in large herds, and take possession of the produce of the husbandman's toil with as little ceremony as though it had been collected for their use."[3]

---

[1] *Voyage to Senegal.*

[2] Griffith's *Animal Kingdom*, vol. i. p. 267.

[3] *The Gardens and Menageries of the Zoological Society delineated*, vol. i. p. 86.

Genus Macacus. Lacep. Posterior molars furnished, as in the preceding, with a fifth tubercle, but the limbs are proportionally stouter and shorter. The tail is likewise shorter, and the superciliary ridges are distinct.

The only example we shall here name is the Wanderou (*M. Silenus*), a large black species, of which the sides of the head and chin are surrounded by a broad beard or ruff, of a dingy white, or pale-grey colour. The tail is terminated by a tuft of hair, on which account it appears to have been named by some the lion-tailed monkey. "The princes and great lords," says Father Vincent Marie, "hold him in much estimation, because he is endowed above every other with gravity, capacity, and the appearance of wisdom. He is easily trained to the performance of a variety of ceremonies, grimaces, and affected courtesies, all which he accomplishes in so serious a manner, and to such perfection, that it is a most wonderful thing to see them acted with so much exactness by an irrational animal." We were never acquainted with more than one living individual of this species, and the only piece of "affected courtesy" it ever exhibited, consisted in nearly biting off the calf of a negro's leg. The Wanderou is a native of Ceylon.

Genus Innuus, Cuv. Characters similar to those of the preceding genus, except that the tail is so short as to seem tubercular.

The well-known Magot or Barbary Ape (*Innuus sylvanus*, Cuv., *Simia innuus*, Linn.), remarkable as the only species of the quadrumanous Order found in Europe, may be adduced as a characteristic example of the present genus. (See Plate I., figure 4.) This species inhabits the rock of Gibraltar, and the nearly opposing point of Africa called Apes Mountain. It does not, however, occur in desert countries, commonly so called; the open sandy plains of Africa being altogether unadapted to the dwellings of this pigmy people. Indeed apes of all kinds are a sylvan race. Their structure being such as to render them unfit for the exercise of rapid movement, either on all-fours, or in an upright position, the intwined and densely intermingled branches of trees are their favourite places of resort. Their feet in climbing being equally useful as their hands, great additional power and activity are thus derived. Among the shady and otherwise unpeopled arbours which skirt the banks of the yet mysterious rivers of Africa, they dwell in single pairs, or in congregated groups, according to the instinct of each particular kind; and seated on the tops of ancient trees, or swinging from pendant boughs, they play their fantastic tricks, secure alike from the wily serpent during the day, and the panther which prowls by night.[1] The species in question, which also inhabits Egypt, is supposed to be the *Pithecus* of ancient writers.

Genus Cynocephalus, Cuv. Canine teeth very strong. Superciliary and occipital ridges very distinct. Head and muzzle lengthened, the latter truncated at the point; nostrils terminal. Face furrowed by longitudinal striæ. Cheek pouches and callosities.

The species which compose this genus, notwithstanding their resemblance in some respects to the human face and figure, are among the most disgusting and degraded of the brute creation. Their colouring is occasionally brilliant, and their fur long and ornamental; yet there is an expression of moral deformity in their aspect, at which we cannot help revolting. Their habits in a state of nature are said to be extremely ferocious, and in confinement their propensities seem all of the most odious kind. Their strength, in comparison with their apparent size, is enormous. By muscular energy alone, and without the assistance of their huge tusks, they will in a few minutes tear the strongest dog to pieces. Fortunately with all their fierceness, they are not carnivorous, otherwise the most dreadful of the feline races would prove less formidable foes. In the wild state they subsist principally on roots and fruits, although eggs and young birds are believed to form a portion of their occasional sustenance. The species are almost exclusively African, and are subdivided into the two following groups.

a. *Tail Long.* Baboons.

The Guinea baboon (*Cyn. Papio*, Desm.), has the fur of a yellowish-brown colour; the face entirely black. The cartilage of the nose exceeds the jaws at its upper extremity. The upper eyelids are white. It occurs on the coast of Guinea.

The pig-faced baboon (*Cyn. porcarius*, Desm.), has the fur of a greenish-black above; the face of a violet black, paler around the eyes; the upper eyelids white. The tail is long and tufted, and, in the adult state, there is a kind of mane upon the neck. It inhabits the Cape of Good Hope. (See Plate I., figures 3 and 3 *a*.)

b. *Tail Short.* Mandrills.

The variegated or ribbed-nosed baboon of English writers (*Cyn. mormon*, Desm., *Simia maimon* and *mormon*, Linn.), is of a greyish olive-brown above, beneath white, with a yellow beard, and blue face; and (in the adult male) a red nose. It is scarcely possible to conceive a more extraordinary looking animal. It possesses great strength, and is said to be much dreaded by the negroes. The well-known "Happy Jerry" of Exeter Change belonged to this species. He was too much addicted to gin and water. We have figured as an illustration of this division, the species commonly called the Drill, *C. leucophæus*, Desm. It is of African origin. (See Plate I., figure 5.)

We here terminate our sketch of the first sub-family, or Simiæ Catarrhini, composed of all the animals of the Ape kind peculiar to the ancient world, and shall now proceed to the

2d Sub-Family.—Simiæ platyrrhini, or Apes of the New Continent.

Six molar teeth on both sides of each jaw, bluntly tubercular, or only five, with acute tubercles.[2] Nostrils opening on the sides of the nose, and separated by a broad partition. Tail always long, and frequently prehensile, that is, endowed with the power of grasping. No cheek pouches, nor posterior callosities. Head usually of a roundish form.

1st Division. *Tail long and prehensile.* The Sapajous.

Genus Ateles, Geoff. Molar teeth 24 in all, with blunt crowns. Facial angle about 60 degrees. Head round; members slender; thumb wanting, or nearly so, on the anterior hands. Tail extremely long and very prehensile, with a bare space beneath at the extremity.

The species of this genus seem to be of a mild, timid, melancholy character, and more indolent in their movements than most of the monkey tribe. A beholder is apt to believe them sick, or in a state of sufferance. It is known, however that, when necessary for their own safety they can exhibit great alacrity. They dwell in troops amid the lofty branches of forest trees, and feed chiefly on fruits; but they are alleged to eat also insects and small fishes, and to have been seen picking up oysters and other testaceous mollusca when the tide was low, and bruizing them between two stones. So at least says Dampier. D'Acosta adds as another trait of their great natural intelligence, that when they wish to pass from one tree to another without descending, they form a lengthened chain by hanging to each other's tails, and swing with a pendulous motion, till one of them catches hold of an opposing branch. The genus is spread over a great extent of South America, and contains a considerable amount of species, some of which (forming the genus *Eriodes* of Is. St Hilaire), in the thin partition of the nostrils, and their downward instead of lateral opening, seem intermediate between the monkeys of the old world, and those of the new.

---

[1] *Edinburgh Cabinet Library*, vol ii. p. 444, 2d edition.

[2] None of the American monkeys have fewer than 24 molars, except the Ouistitis (*Hapale*, Illiger), in which the amount is the same as in the species of the Old World, i. e. 20.

a. *A very small, or rudimentary anterior thumb.*

The Miriki monkey (*Ateles hypoxanthus*, Kuhl) is a species discovered in Brazil by Prince Maximilian of Neuwied. The fur is of a yellowish-grey colour, the face flesh colour, with grey spots. In some specimens the anal region and origin of the tail are rusty red. The miriki greatly resembles the spider monkey (*A. arachnoides*, Geoff.), but the latter wants the rudimentary thumb. The only other species of this subdivision is the *Ateles subpentadactylus* of Desm., the *Chamek* of Buffon.[1] It has no nail upon the rudimentary thumb.

b. *No rudimentary anterior thumb.*

The Marimonda monkey of Humboldt (*Ateles Beelzebub*, Geoff.) is one of the most noted species of this subdivision. The fur is brownish-black above, of a dingy or yellowish-white on the abdomen. It is one of the most common species in Spanish Guiana, and occurs in immense numbers along the wooded banks of the Oronooko, where they are seen hanging as it were in festoons, suspended from the branches, and holding by each other's hands or tails. They are also sometimes observed for hours at a time, sitting with heads upraised, and folded arms, exposing themselves to the scorching rays of the noon-day sun. The prehensile power of the tail is remarkable in this species, and probably makes amends (in accordance with that providential arrangement which the French naturalists designate as *la loi du balancement des organes*) for the somewhat defective structure of the anterior hands. The marimonda is frequently used as food in South America, and would be speedily relished even by strangers, but for the child-like aspect of the heads, which, when turning round in a tureen of soup, give rise to most extraordinary and unpleasant associations. There are about ten species of *Ateles* described by naturalists, including those which constitute the genus *Eriodes* of M. Isid. St Hilaire.

Genus Lagothrix, Geoff., Humb. Amount of molar teeth as in Ateles. Facial angle about 50 degrees. Muzzle projecting, head round. Thumbs on all the extremities. Hair soft and frizzly.

Of this genus there are not more than three species known, and one of these is doubtful. Little has been ascertained of their natural economy. They are gentle in their dispositions, of gregarious habits, and are usually seen sitting on their hind legs.

Genus Mycetes, Illiger. Teeth the same in number as in the preceding genera, but the canines are more developed. Facial angle scarcely more than 30 degrees. Head pyramidal, visage oblique. Hyoid bone much enlarged, cavernous, and producing externally an inflation of the throat. Nails short and convex.

The species of this genus known under the name of Alouattes, or howling monkeys, are the largest and fiercest of the quadrumanous tribes of South America. Their powers of voice are extraordinary, and result, we doubt not (though no detailed demonstration of the fact has yet been afforded) from the peculiar construction of the hyoid bone, and the parietes of the larynx.[2] "Though the animals of the American continent differ in many material points from those of the old world, yet is there almost always a general analogy between them, an analogy sometimes also observable even between the minor subdivisions. We might be justified, for example, in calling the Alouattes, or howling monkeys, the baboons of the new world. They approximate to them in size and fierceness, and are perhaps still less susceptible of culture, and still less amenable to the discipline of man. They are in truth distinguished for wildness and ferocity, and the bony structure in their throats, which gives to the voice such tremendous force and volume, adds in no small degree to the terror which they are otherwise calculated to inspire. They wander in large troops, chiefly in the night, and make the vast forests resound with their dreadful yellings. What heightens the effect is, that they howl in concert; the entire herd joining in one deafening cry the instant they discover the approach of an intruder."[3]

Some of the species of our present genus are so numerous, that Humboldt has counted forty on a single tree, and his calculation is, that in certain districts more than 2000 exist in one square league. We receive various and somewhat contradictory statements of their history and habits from different travellers. All agree that a practised marksman is required, whether with bow and arrow or *les armes à feu*, to bring them to the ground, because, unless shot at once through the brain, their prehensile tail immediately entwines itself around a branch, and keeps its owner suspended even after death, unless that event is almost instantaneous. The females appear to produce only a single young one at a time. According to Azzara, the mother when alarmed is apt to abandon her offspring, and various other voyagers report that the instinct of maternal love is less pervading in our present tribe than among the majority of monkeys. The traveller Spix, however, relates that he mortally wounded a female, who continued to carry her offspring on her back, till she was about to expire from loss of blood, when, by a last effort, she threw her precious burthen among the neighbouring branches, and fell exhausted to the ground. Oexmelin, the author of "l'Histoire des Aventuriers," also alleges that the female howlers are remarkable for their attachment to their young; that they succour and assist each other under various difficulties; and that when one is wounded, the rest assemble around him full of compassionate sympathy, and even attempt to stop the flowing of the life-blood from the perforation of the deadly bullet. "I have witnessed this," says the author, "many times with admiration." It is certainly one of the advantages of travelling into "far countries," that one is thereby enabled to see many wonderful sights, of a nature seldom seen at home. Spix states that the howlers are monogamous. Azzara is of a contrary opinion. It is admitted that they spring with great agility from branch to branch, confiding in the powers of their prehensile tail, should their quadrumanal efforts prove fallacious. They live on fruits and insects, and seem to delight more than others of their kind in the vicinity of streams and marshes. Hence they roam either along the banks of rivers, or among those wooded islands of the moist savannahs, which are subject to frequent inundations. They even inhabit, according to Legentil, the marine Ile Saint George, two leagues from the main land. The howlers are rarely reared in captivity, their dispositions being unamiable, their voices unendurable, and their natural instinct little susceptible of amelioration by the human race. It is probably for these reasons that we scarcely ever find them brought alive to Europe, notwithstanding our constant commercial intercourse with the countries which they inhabit. Naturalists do not seem to be well acquainted with more than seven species of howlers. For their detailed descriptions we must refer the reader to the writings of Marcgraaff, Azzara, Geoffroy, Humboldt, Kuhl, Desmarest, and Spix.[1]

---

[1] A curious anomaly has been observed in a specimen of *Chamek*, viz. the existence of seven grinders on the right side of each jaw.

[2] See Humboldt in *Observations Zoologiques*, and the *Diction. Class. d'Hist. Nat.* t. xv. p. 131.

[3] Griffith's *Animal Kingdom*, vol. 1. p. 301.

Genus Cebus, Erxleben. Teeth the same in number as in the preceding genera, but the upper incisors are broader than the under. The head is round, the muzzle short, the forehead slightly prominent, the occiput projecting backwards. Facial angle about 60 degrees. Ears rounded. Hyoid bone not inflated. Anterior thumb elongated. Tail prehensile, but furred throughout its entire extent.

In this genus, which includes the Sapajous properly so called, the members are strong and lengthened, especially the hinder extremities. They consequently leap about with great activity. Like their congeners they are gregarious, and live in trees. Their disposition is lively, but less petulant than that of the guenons of the Old World. Their cranial development is large, and their intelligence proportional. They are easily tamed, and very tractable. Our knowledge of their natural history is very slight, most of the facts by which we could illustrate their habits having been drawn from the observance of their captive state. The younger St Hilaire informs us that they indulge in abstract ideas, his proof being that he once observed a Sapajou, which had met with a nut somewhat harder than usual, descend from the top of a wooden cage, and crack the said nut by bruising it against an iron bar. "Cette observation," he remarks, "nous paraît digne d'être citée; car elle prouve d'une manière incontestable que notre sajou abandonné à lui-méme et sans avoir jamais reçu aucune éducation, avait su reconnaître que la dureté du fer l'emporte sur celle du bois, et par consequent, s'etait élevé à un rapport, *à une idée abstraite*." It is delightful to find metaphysics thus combined with natural history. The Sapajous are rather omnivorous in their propensities, for although they feed chiefly on fruits, they are also avidous of insects, worms, and mollusca. The species occur principally in Brazil and Guiana, and are sometimes known under the name of musk-apes, from a peculiar odour which they emit during the rutting season. They have also been denominated *weepers*, from their occasional utterance of a certain plaintive and disconsolate cry.

The sapajous of our present genus, as M. Desmarest has well observed, are extremely difficult to characterize. Their size and general form and aspect exhibit a great similarity, and authors differ considerably as to the amount of species. Brisson describes three, Linnæus four, Gmelin six, Buffon two, and recent authors (Kuhl, Humboldt, Desmarest) above a dozen. We must here, however, content ourselves with the preceding generalities, and a slight indication of one or two species.

The most familiarly known in this country in the living state, is that called the weeper monkey (*Cebus apella*, Desm.) (Plate I., figure 6.) The fur of this species is of a brown colour, deeper above than below. The face is brown, encircled by darker brown hairs. The top of the head, tail, and feet are blackish-brown. This species inhabits Guiana, and is of a hardy, playful, and contented disposition. It sometimes breeds in confinement.

The white fronted sapajou (*Cebus albifrons*, Desm.) has the fur of a grayer colour than that of the preceding. The top of the head is black, the front and orbits white, the extremities of a brownish-yellow. This species, the ouavapavi of Humboldt, is found in troops near the cataracts of the Oronooko. It is a great favourite among the natives, on account of its gentle docility, and the pleasing and elegant alacrity of its movements. A tame one observed by Humboldt at Maypures, seemed to have acquired indolence by domestication. It was in the habit of catching a pig every morning, and continued sitting on its back throughout the day, while it fed in the neighbouring savannahs.

2d Division. *Tail long, but not prehensile.* The Sagouins.

The Sagouins, in general, are distinguished from all the preceding genera of American monkeys, by their tails being destitute of the prehensile or grasping power; and this deficiency, trifling though it seems, brings with it a considerable change of character. Being unable to suspend themselves from the far branches of forest trees, they more frequently seek protection in the denser brush-wood, or among the escarpments of rocky banks. The structure of their eyes seems well adapted for nocturnal vision.

Genus Saguinus, Lacép. *Callithrix*,[2] Geoff. Cuv. Desm. Canine teeth of medium size, lower incisors vertical, and contiguous to the canine. Head small and rounded; muzzle short. Facial angle 60°. Partition of the nostrils not so broad as the range of the superior incisors. Ears very large.

We have acquired as yet a very limited knowledge of the natural habits of this genus. It is ascertained that the species exhibit great intelligence (which might almost be inferred from the large development of the cranium), feed on fruits and insects, and dwell gregariously among the equatorial forests of the New World.

The type of this genus is the beautiful Saimiri of Buffon, the squirrel monkey of our English authors (*Saguinus sciureus*). It is a small and elegant species, of an olive-gray colour, the muzzle black, the legs and arms bright red. It is remarkable for its rounded head, and the flatness of its visage. Its physiognomy is extremely like that of a human infant, but much more pleasing than that of many. It has the same expression of innocence, mingled occasionally with something more malign, and in its expression there is the same frequent and rapid alternation from joy to sorrow. When chagrined, its little eyes are seen to fill with tears. It inhabits Brazil and Cayenne, and is common to the south of the cataracts of the Oronooko, and along the wooded shores of the Rio-Guaviaré. The natives hold it in great request, on account of its beauty, its docile manners, and the general sweetness of its disposition. It is among the most restless of living creatures, but its every movement is full of grace. It is extremely fond of spiders and other insects, and Humboldt observed it exhibit an amusing though mistaken sagacity, in singling out some engravings of these tribes, and endeavouring to pick them off the paper with its paws.[3] It exhibits remarkable adroitness in the capture of living insects, and, under proper culture and control, might possibly be made a very useful *aide-du-camp* to an entomological collector. The young refuse to abandon the dead body of their bleeding mother, and it is only through the strength of this beautiful instinct that they can be captured alive. The affection, according to Geoff. St Hilaire, corresponds with the large development of the posterior lobes of the brain. The individuals appear to vary considerably with age or other circumstances.

A much rarer species of the genus is the widow monkey (*Saguinus lugens*), of which the colour is blackish, the throat and fore-hands white. The fur of this creature is very soft and lustrous, the character melancholic, the habit solitary. It dwells in the forests of the Cassiquiare and the Rio-Guaviaré, and is also found among the granitic mountains of the right bank of the Oronooko, behind the mission of Santa Barbata. Several other species are well known to naturalists.

---

[1] See also the article *Sapajous*, in *Diction. Class. d'Hist. Nat.* t. xv. p. 131.

[2] We adopt the generic title of *Saguinus* long since proposed by M. Lacépède, both on account of its prior claim, and its being a less inappropriate name than *Callithrix* (an ancient *Homeric* appellation) for an *American* group.

[3] *Recueil d'Observ. Zool.* p. 322.

Passing over the genus *Nocthores* of F. Cuvier (*Aotus*[1] of Illiger), which contains the curious nocturnal monkey called Dourouculi by the natives of the Oronooko, we come to the more extensive

GENUS PITHECIA, Desm. Incisive teeth approached, the superior oblique and broad, the inferior long and narrow, converging towards their points, and separate from the canines. Canines strong. Partition of the nostrils broad. Head round, muzzle short. Facial angle about 60 degrees. Ears of medium size, margined, and in form resembling those of the human race. Tail clothed with long hair. Nails short and curved.

The species of this genus are known under the various names of Sakis, fox-tailed monkeys, night-monkeys, &c. They are not strictly nocturnal, but move about chiefly during the evening twilight and the early morn. They inhabit the forests of Brazil, Guiana, and Cayenne, and live on fruits and insects. Their habits are but slightly known, probably in consequence of their seldom stirring much abroad throughout the day. They are said to dwell in small groups of seven or eight individuals, and search with avidity for the nests of wild bees. (See Plate II., figure 1.)

Naturalists are acquainted with eight or nine species of Saki. The only one we shall here allude to is the hand-drinking saki (*Pithecia chiropotes*, Humb.), so called from its peculiar mode of imbibition. It lifts the water in the hollow of its hand, and, leaning its head to one side, conveys the liquor to its mouth. It becomes almost furious when its beard is wetted, an aversion which has probably induced it to adopt the peculiar habit just mentioned, but from what principle this aversion springs, we are not prepared to say. The fur of this singular creature is of a chesnut-red colour. It has a long tufted beard, and a thick bush of hair, separated in the middle, and hanging down on each side of the head. In Humboldt's opinion, it more nearly resembles the human race than any other monkey of America. Its eyes, according to that author, have an expression of melancholy mixed with ferocity. It is, moreover, robust, active, untameable, and, when irritated, will raise itself upon its hinder extremities, grind its teeth, stroke down its beard as if it were a Turk, and fly at the offending person with a fury quite unbecoming the semblance of South American humanity. Yet it is habitually melancholy, and, in the captive state, is never excited to gaiety, unless it may be for a few brief and hungry moments at the sight of some favourite food. Why, indeed, should it be gay, pent up in some wretched crib, a collared slave, far from its "friends and brothers," and destined never more to swing from lofty and umbrageous boughs, nor listen from the depths of darkened forests to the roaring cataracts of the Oronooko, where all its "young barbarians are at play?"

GENUS JACCHUS, Geoff. Desm. Incisive teeth $\frac{4}{4}$, canines $\frac{1-1}{1-1}$, molars $\frac{5-5}{5-5}$ (sharply tuberculated); $= 32$. Thumb of the anterior hands not opposable to the fingers. Nails long, compressed, and pointed, except upon the hinder thumbs.

The beautiful and graceful creatures which constitute our present genus (of which the striated monkey of Pennant, *Jacchus vulgaris*, Geoff. (see Plate II., figure 2), may serve as a familiar example), differ in the number of their molar teeth from all the preceding genera of American Quadrumana.[2] Their habits are equally arboreal, although in climbing trees, they are supposed to make use of their pointed nails, somewhat after the manner of squirrels, a tribe of animals to which, in several other respects, they bear resemblance. Their natural history, properly so called, is little known, most of the facts narrated in books being drawn from the observation of individuals in the domestic state, to which they are frequently reduced, on account of their small size and great beauty. M. Audouin of Paris had a pair of ouistitis (for so these creatures are often called) for some time in his possession, and made several curious observations on their faculties and dispositions. They not only recognised themselves and each other in a glass (a perception denied to the sagacious dog), but even detected the nature of various animals as represented in paintings. Thus, the representation of a cat alarmed them exceedingly; and although they were so exceedingly fond of insects as to dart greedily at crickets and cock-chafers, yet the likeness of a wasp made them suddenly withdraw their little paws. On one occasion while sucking some grapes, one of them happened to squirt a little of the juice into its eye, since which occurrence it never tasted of that fruit without carefully closing the organs of vision, thereby exemplifying the association of ideas. These ouistitis captured and devoured all kinds of flies with the most inconceivable dexterity, but exhibited a strong instinctive fear of wasps,—the French species being at the same time quite different from any they could have ever seen among the foliage of their native forests. They were extremely fond of sugar, eggs, and roasted apples; but they refused all kinds of almonds, acidulated fruits, and such kinds of leaves as are usually eaten as salads. Neither were they fond of flesh; yet if a small living bird was placed within their reach, they immediately captured it, put it to death, and scooped out its brains.

The species are numerous, and are usually divided into two groups,—the Ouistitis properly so called (*Jacchus*, Geoff.), and the Tamarins (genus *Midas* of the French author). To the former belongs the species above alluded to,—to the latter (besides the silky monkey of Shaw), the small and beautiful leonine monkey described by Humboldt.[3] We deem the line of demarcation somewhat doubtful. The distinctive characters are taken chiefly from the incisive teeth. Good figures of the Quadrumana occur in Audebert's great work *Singes et Makis*, fol., Paris, an. viii.

FAMILY II.—LEMURIDÆ.

The second family of the Quadrumanous Order exhibits a nearer approach to the ordinary quadrupedal form than the preceding. Their incisive teeth (never more than eight in the SIMIADÆ), vary in number in different genera. The nostrils are situate at the extremity of the muzzle. The posterior extremities exceed the anterior in length. All the thumbs are well developed, and capable of being opposed in seizure to the fingers, and the fore finger of the hinder hands is furnished with a lengthened claw-like nail. All the other nails all flat. The mammæ, which are pectoral, range from two to four. Tail never prehensile—sometimes wanting. This family is composed chiefly of the genus *Lemur* of Linnæus, and may be said to bear the same relation to that genus, as *Simia* of the same author does to the preceding family,—thus affording another of the numerous proofs which might be adduced of his surprising tact in the formation of natural groups, and of the manner (not seldom unacknowledged) in which he has prepared the great landmarks for posterity.

---

[1] The name of Aotus was bestowed in consequence of the erroneous supposition that the animal in question had no external ears.

[2] This highly important distinctive character seems to have been entirely overlooked by the majority of systematic writers.

[3] *Recueil d'Observ. Zool.* p. 14. pl. 5. See also, in addition to the different authors named above, Mikan's *Delectus Floræ et Faunæ Braziliensis*, and the *Diction. Class. d'Hist. Nat.* t. xii. p. 512.

Genus Indris, Lacep. *Lichanotus*, Illiger. Incisive teeth $\frac{4}{4}$, canine $\frac{1-1}{1-1}$, molar $\frac{5-5}{5-5}$; $= 32$. Two pectoral mammæ. Head long, and triangular. Fur woolly.

This genus consists of only two species, both natives of Madagascar, where they were discovered by M. Sonnerat. The best known is the *Indris brevicaudatus* (*Lemur Indri*, Linn.), so called on account of the shortness of its tail. (See Pate II., figures 3 and 3 *a*.) This species is an animal of about three feet long, the general colour of the fur blackish, the face and abdomen grey, the tail, and a spot at its base, dingy white. Its natural habits are little known, although in a state of captivity it is gentle and intelligent, and, when taken young, susceptible of being trained to various useful purposes. If Sonnerat is correct in stating that it is used by the natives of Madagascar, instead of a dog, in the sports of the field, it certainly affords one of the most remarkable examples of the subduing influence of the human race. It is itself a frugivorous creature, an inhabitant of the forest, and a habitual dweller in the tops of trees,—yet under the guidance of man it is induced to assume the nature and propensities of a carnivorous species, and to pursue and capture other living animals. However, we rather doubt the fact. Its voice is said to resemble that of a weeping infant. The other species, distinguished by its lengthened tail, and the yellow colour of its fur, is the flocky lemur of Shaw (*L. laniger*, Gmelin).

Genus Lemur, Lin. Cuv. Incisive teeth $\frac{4}{6}$, canine $\frac{1-1}{1-1}$, molar $\frac{6-6}{5-5}$; $= 36$.[1]

The peculiarities observable in the dentition of this and certain allied genera, may, in the opinion of some naturalists, be thus explained. The six incisor teeth of the lower jaw are long, slender, and almost horizontal, the outer one on each side being, however, larger than the others, and of a somewhat different form. These may therefore possibly represent the canine teeth,—the more especially as the pair usually so considered do not meet those of the upper jaw, but are farther back, and bear much of the character of false molars. If they were to be so regarded, then the dentition of the lemurs would resemble that of the generality of American Quadrumana, which possess an additional molar, but the same number of incisors with those of the ancient continent.

The singular animals known under the name of Lemurs, inhabit the island of Madagascar, where they seem to occupy the place of monkeys, the latter being there unknown. They likewise occur in the not distant island of Anjouan, one of the group of the Comora Archipelago. The ring-tailed species (*L. catta*, Linn.), is one of the most elegant of the genus,—its motions being characterised by a great degree of lightness, its manners mild, its nature very harmless. In size it equals a large cat; the hair is extremely soft and fine, and the tail, which is about twice the length of the body, is marked by numerous alternate rings of white and black. It is gregarious in the wild state, travelling in small troops of thirty or forty. It is easily tamed when taken young, delights in sunshine, but within doors prefers a good place at the fireside to any other quarter. It is frequently brought alive to Europe; and an individual, whose acquaintance we happened to make in France, had lived there for nineteen years. It sometimes sat so near the fire in winter as to singe its whiskers. The white-fronted lemur (*L. albifrons*), has been known to breed in Europe. The ruffed lemur (*L. macaco*, Linn.), is another well known species, remarkable for the extraordinary strength of its voice, which is said to strike with fear and astonishment those who hear it for the first time. It may be likened to that of the Araguata, one of the howling monkeys of America, which fills the lonesome woods of Guiana with its wild and dreadful cries. We have figured *L. ruber* of Peron. (See Plate II., figures 6 and 6 *a*.)

We have few generalities to state regarding the Lemur tribe, for they have been very sparingly observed in their native haunts. They live on trees, feed on fruits, and resemble squirrels in their attitudes. In a domestic state they are gentle, and attached to their friends, but shy of the society of strangers. This shews their good sense.

Genus Loris, Geoff. *Stenops*, Illiger. Teeth as in the preceding, but the molars are provided with sharper points. Eyes large and approximate. Tongue rough. Ears short and furred. Tail wanting, or very short. Four pectoral mammæ.

This genus, as now constituted, contains only two species (*Lem. gracilis* and *tardigradus*, Linn.), both natives of the East Indies.[2] In these animals we perceive an obvious tendency towards carnivorous habits, and a departure from the character of the preceding tribes. They are said to prey very much on insects and birds, and even on the smaller quadrupeds. Their motions are extremely slow, and their mode of life nocturnal. We have represented the species last named on Plate II., figure 4.

Genus Galago, Geoff. *Otolicnus*, Illiger. Incisive teeth $\frac{4 \text{ or } 2}{6}$, canines and molars as in the preceding. Ears large, and naked. Hind legs extremely long. Tail also long. Two pectoral mammæ.

The galagos inhabit Africa and Madagascar. We know little of their natural habits. They live in trees, and are said to feed on insects. The Senegal galago (*G. Senegalensis*, Plate II., figure 7), is called the gum animal by the Moors, probably on account of its occurring so frequently in the forests of gum trees which border the Sahara. It is alleged, however, to eat the gum freely, although there is no doubt of its insectivorous propensities. It is a small animal of the dimensions of a rat, with a very long tail. The species are as yet but ill defined, and Geoffroy has greatly erred in placing the Fennec of Bruce among the galagos.

Genus Tarsius. Storr. Cuv. Incisive teeth $\frac{4}{2}$, canine $\frac{1-1}{1-1}$, molar $\frac{6-6}{6-6}$; $= 34$. Head round, almost spheroidal. Eyes excessively large, and contiguous. Ears long, naked, membranous. Tarsus three times the length of the metatarsus. Nails subulate on both the second and third fingers of the hind feet.

Of the three species which compose this genus, two (*Tarsius Bancanus*, Horsfield, and *T. spectrum*, Geoff.), inhabit the Moluccas, the other (*T. fuscomanus*, Fischer), is a native of Madagascar. Their habits are nocturnal and insectivorous.[3] For their external aspect and teeth see Plate II., figures 5 and 5 *a*.

---

[1] The number of molar teeth in this genus is variously stated by different authors. Baron Cuvier gives "six molaires de chaque coté en haut, six en bas."—*Règne Animal*, t. i. p. 107. His brother M. Fred. gives only five for each side on the lower jaw.—*Dens des Mammifères*, p. 24. M. Desmarest assigns five on each side for the upper jaw, but only four on each side for the under. We have stated the number which most coincides with our own observations.

[2] M. Geoffroy St Hilaire (in *Ann. Mus.* t. xix. p. 164), includes the slow lemur of English authors (*L. tardigradus* above named), in his genus *Nycticebus*.

[3] An animal of a very peculiar nature, described as a squirrel by Gmelin, and now forming the Genus *Cheiromys* of naturalists, is placed by some in the Quadrumanous Order. It has, however, only two incisive teeth in each jaw; and we therefore prefer treating of it in a subsequent part of this article, as a member of the Order Rodentia.

ORDER II.—FERÆ.

This order, as now constituted (and corresponding to the CARNASSIERS of Baron Cuvier), contains all the FERÆ, and several of the PRIMATES, of the Linnæan system. The species of which it is composed are characterized by possessing, in common with the Quadrumanous Order, three kinds of teeth, viz. incisors or cutting teeth, canine teeth or tusks, and molar teeth or grinders; but they are distinguished from that order by the different form of their claws, and by never having a flexible thumb opposable to the fingers or toes of either extremity.

The most general attributes of the organic form of the ferine animals are the following: 1*st*, The shortening of the intestinal canal; 2*d*, The increased size and sharpness of the canine teeth, and the cutting or frequently pointed form of the molars; 3*d*, The shortness of the lower jaw, and its peculiar articulation, which (combined with the *locking* of the teeth when closed), is such as to admit only of vertical motion. The term molar or grinding, therefore, cannot with accuracy be applied to the lateral or posterior teeth of strictly carnivorous animals, which masticate their food by biting it in pieces, but cannot triturate or grind it like the purely herbivorous kinds.[1] 4*th*, The double convexity of the zygomatic arch of the temporal bone, and the depression of the parietal towards the axis of the head, to afford space for the insertion of the temporal-maxillary muscles, of which the bulk increases with what may be called the *carnivority*. Characters deduced from the size or even form of the claws are of less avail,—seeing that both the power and dimensions of these parts are increased in most of the Edentata, among which the organization of the teeth and jaws follows an inverse proportion. In the cat-kind, however, the shape of the claws is extremely characteristic.

The degree of each of the four anatomical characters above alluded to, and their combination, more or less complete, determine the degree of carnivority,—with which that of ferocity usually corresponds. We must not, however, attach to the word ferocity the idea of any fatal or irresistible necessity to murder,—for the instinct to destroy is only the sensation of hunger in animals having a propensity to flesh, and provided with the means of obtaining it. It requires, indeed, a little more determination and activity, with, it may be, more malignity of movement, for one animal to seize upon and devour its neighbour, than for another animal to masticate a turnip,—but each is acting in obedience to its natural instincts, and neither is following the dictates of a depraved appetite.

As in all other great groups, we have here various modifications of the typical character. Several bats are frugivorous, though in their general structure too closely allied to their congeners to be removed from the ferine order; while various bears and badgers are extremely accommodating in their dispositions, and will eat freely enough of vegetable substances rather than starve. The general form and aspect of this order are also highly varied. Some are organised for flight, as the Cheiroptera; others for swimming and diving, as the seals and morses; while several are subterranean, as the moles. We do not find such a diversity in the sphere of existence among the pachydermatous and ruminating tribes. The geographical distribution of the order is unlimited, so that we cannot connect flesh-eating propensities in any way with climate. If the lion and the tiger haunt habitually the torrid zone, the polar bear,

> "With dangling ice all horrid, stalks forlorn"

along the frost-bound shores of Greenland. Thus heat and cold have no more influence over the nutritive appetite, than over the warmth of the instinct of love,—which rules supreme alike amid perennial snows, and beneath the unmitigated glare of equatorial suns.

We arrange the genera of the Ferine Order under four principal divisions, viz. CHEIROPTERA, INSECTIVORA, CARNIVORA, and MARSUPIALIA.

DIVISION I.—CHEIROPTERA.

The most remarkable and striking peculiarity of this group consists in the membranous expansion which pervades the sides of the body, connecting the anterior and posterior extremities, and, in many cases, the latter, with the tail. This structure enables almost all the species to fly like birds, although with less activity and power; and the exercise of such a function of course requires a modification of other parts, such as great strength of clavicle and breadth of shoulder-blade, for the production of the requisite solidity. It is, however, incompatible with the rotation of the fore-arm, which would have enfeebled the force of the flying action.

The Cheiropterous division is composed of two families, the VESPERTILIONIDÆ and the GALEOPITHECIDÆ.

FAMILY 1ST.—VESPERTILIONIDÆ, OR BATS.

In this family the fore-arms and fingers are excessively elongated, and the interstices of the latter being filled up by the membrane already alluded to, which also extends backwards to the hind feet, genuine wings are thus provided, more expansive even than those of birds. The pectoral muscles are extremely thick, and the sternum has a central ridge for their attachment, resembling that of birds. The thumb is short, and armed with a hooked nail, by means of which the species climb or suspend themselves. Their hind feet are rather feeble, furnished with five toes, almost always of nearly equal size, and armed with pointed and sharp-edged nails. The eyes are proportionally very small, but the external ear is usually very large, partaking, as it were, of the expansive nature of the lateral membrane, and in common with it is naked, or nearly hairless. This membrane, whether in the form of auricle or wing, is supposed to be endowed with a very exquisite perceptive power—sufficient to guide the flying creature through labyrinths of subterranean darkness, and even, according to Spallanzani, to wing its intervening way through various obstacles, after it has been totally deprived of sight. This power is presumed to result from the perception, by the nerves of the cutaneous system, of the refluxes of air from near opposing bodies.

---

[1] There seems to be no very satisfactory or explicit nomenclature of the teeth of ferine animals. False molars, carnivorous cheek-teeth, and tubercular grinders, are probably the most precise and applicable terms which can be employed to discriminate the different kinds of molar teeth, commonly so called, which distinguish the family Carnivora; and these terms have the additional advantage of corresponding closely with the nomenclature proposed by M. Fred. Cuvier, and adopted by his illustrious brother in the *Règne Animal.* In the Genus *Felis*, for example, there are four molar teeth in the upper, and three in the under jaw. Of these the two anterior, both above and below, are the most cutting, and are called the false molars (*fausses molaires* of Cuvier). They are followed by a very large tooth, which, in the upper jaw, is furnished with three points or lobes, in the under with only two. This is the carnivorous cheek-tooth (*carnassière*). Behind it, in the upper jaw, is a small flattish tooth (*la tuberculeuse*), which may be named the tubercular grinder. In animals of the cat kind there is no corresponding separate tooth of the last description in the lower jaw; but its function is performed by the inner projecting lobe of the under carnivorous cheek-tooth, the rounded point of which, when the jaws are closed, is applied to the flat surface of the upper tubercular grinder. In the canine race, however, there are two tubercular teeth on both sides of either jaw, and it is with these that they chew the grass which they so frequently swallow. In the tribe of bears the false molars, instead of being more or less compressed and cutting, are entirely tuberculated; and, in perfect accordance with this structure, they are known to be the least carnivorous of the family to which they belong: indeed, the disposition and habits of an animal may be correctly deduced from the greater or less prevalence of the cutting or tuberculated character of the molar teeth.

Bats are nocturnal, or at least twilight loving animals, which in northern countries pass the winter in a state of lethargic repose. From this state of hybernation, however, they are easily roused, and it is no uncommon thing to see our smaller species flitting about in a winter afternoon, during the occurrence of a milder day than usual. However, the then almost total absence of moths and flies must render such occasional excursions on the whole enfeebling, by exciting the digestive and other functions (previously at rest), without, at the same time, affording the means of sustentation. During the day they hang suspended from the roofs of barns and other buildings, or in crevices of ruined castles, or find shelter beneath the murky canopy of caves, or the overhanging gloom of shaded rocks. Neither do they despise the secure concealment afforded by the hollow chambers of ancient forest trees, whether rent by the "red lightning's glare," or yielding imperceptibly to slow decay. They usually produce two young at a birth, which adhere tenaciously to their mother, and are frequently borne about by her during her twilight flights.

The species (including the various genera, of which our narrow limits will enable us to give but a brief account), are extremely numerous,—above 130 different kinds being known to naturalists. The majority inhabit the regions within the tropics, and none occur in the countries of the extreme north; neither are we aware that any have yet been observed in New Holland. When the "knell of parting day" announces the approach of the long continuing twilight of our temperate regions, we see our own diminutive species flitting about on leathern wings, or dimpling the surface of the still waters, in search of insects or other natural prey; but these give us but a feeble idea of the monstrous forms which inhabit equatorial countries. Many of the genera are extremely circumscribed in their geographical distribution, either owing to their nocturnal habits, or their powers of flight being unequal to a long sustained migration. We may add, that all bats possess four well developed canine teeth, but that the incisors differ in number in the various genera. Of a few of these we shall endeavour to exhibit the principal characteristics.[1]

GENUS PTEROPUS, Brisson, Cuv. Incisive teeth $\frac{4}{4}$, canine $\frac{1-1}{1-1}$, molar $\frac{5-5}{6-6}$; $= 36$. Form of the incisors conical; canines rather large; molars with the crown obliquely truncated, and marked by a longitudinal groove. Head long and conical. Ears short, simple, and without any tragus.[2] No peculiar appendages upon the nose. Tail short or wanting. Interfemoral membrane deeply incised. The index finger, with three phalanges and a rudimentary nail. The tongue papillose. (See Plate III., figures 4 and 6.)

The species of this genus, called *Roussettes* by the French, are of a frugivorous regimen, feeding on pulpy fruits, especially bananas. They are confined to the ancient world,—occurring chiefly in the islands of the Indian Archipelago, Bengal, Madagascar, the Isle of France, and several parts of Africa. They are the largest of all the bat tribe, and certain species measuring between five and six feet from tip to tip of the extended wings.

The eatable roussette (*Pt. edulis*) is of a blackish colour, deeper on the breast than back. It is a large species, measuring about five feet in extent;—the body sixteen inches long. Its flesh is white and delicate, and is held in great esteem as an article of food by the natives of the Island of Timor. It seems to vary in its external character with age, and has been accordingly described under different names. Thus the *Kalong* of the Javanese (*Pt. Javanicus*, Horsfield) is regarded as identical. It is a gregarious species, very abundant in the lower parts of Java. "Numerous individuals," says Dr Horsfield, "select a large tree for their resort, and suspending themselves with the claws of their posterior extremities to the naked branches, often in companies of several hundreds, afford to the stranger a very singular spectacle. A species of ficus, in habit resembling the Ficus religiosa of India, which is often found near the villages of the natives, affords them a very favourite retreat, and the extended branches of one of these are sometimes covered by them. They pass the greater portion of the day in sleep, hanging motionless: ranged in succession, with the head downwards, the membrane contracted about the body, and often in close contact, they have little resemblance to living beings, and by a person not accustomed to their economy, are readily mistaken for a part of the tree, or for a fruit of uncommon size suspended from its branches. In general these societies preserve a perfect silence through the day; but if they are disturbed, or if a contention arises among them, they emit sharp piercing shrieks, and their awkward attempts to extricate themselves, when oppressed by the light of the sun, exhibit a ludicrous spectacle. In consequence of the sharpness of their claws, their attachment is so strong that they cannot readily leave their hold, without the assistance of the expanded membrane; and if suddenly killed in the natural attitude during the day, they continue suspended after death. It is necessary, therefore, to oblige them to take wing by alarming them, if it be desired to obtain them during the day. Soon after sunset they gradually quit their hold, and pursue their nocturnal flights in quest of food. They direct their course, by an unerring instinct, to the forests, villages, and plantations, occasioning incalculable mischief, attacking and devouring indiscriminately every kind of fruit, from the abundant and useful cocoanut, which surrounds every dwelling of the meanest peasantry, to the rare and most delicate productions, which are cultivated with care by princes and chiefs of distinction. By the latter, as well as by the European colonists, various methods are employed to protect the orchards and gardens. Delicate fruits, such as mangos, jambus, lansas, &c., as they approach to maturity, are ingeniously secured by means of a loose net or basket, skilfully constructed of split bamboo. Without this precaution, little valuable fruit would escape the ravages of the kalong.

"There are few situations in the lower parts of Java in which this night wanderer is not constantly observed. As soon as the light of the sun has retired, one animal is seen to follow the other at a small but irregular distance, and this succession continues uninterrupted till darkness obstructs the view. The flight of the kalong is slow and steady, pursued in a straight line, and capable of long continuance. The chase of the kalong forms occasionally an amusement to the colonists and inhabitants during the moonlight nights, which, in the latitude of Java, are un-commonly serene. He is watched in his descent to the fruit-trees, and a discharge of small shot brings him readily to the ground. By this means I frequently obtained four or five individuals in the course of an hour, and by my observations I am led to believe that there are two varieties which belong to one species, as they appear all to live in one society, and are obtained promiscuously."[1]

---

[1] The student who desires a detailed acquaintance with the Cheiropterous tribes, will study with advantage the systematic exposition given by M. Desmarest, in his *Mammalogie*, and M. Geoffroy St Hilaire's papers in the *Annales du Mus.* The English reader is referred to Mr Griffith's Translation of the "Animal Kingdom," (particularly the *Supplementary Essay*, vol. ii. p. 84, and *Synopsis*, vol. v. p. 54).

[2] We apply the term *tragus* to that secondary leaf-like expansion, which in many bats covers or protects the auricular opening. It is the part named *oreillon* by the French writers.

A roussette (we know not the exact species) brought alive to France about the beginning of the present century, was observed to remain constantly calm and motionless throughout the day, suspended by one of its hind feet. Yet Quoy and Gaimard report that they saw these great bats flying during the day in the Carolina Islands, and Messrs Lesson and Garnot have made the same remark as to their diurnal powers. These notices are the more interesting, as they confirm the statements of the earlier voyagers.

The vampire bat, commonly so called, (*Vespertilio vampyrus*, Linn.,) belongs to the genus Pteropus. Having already alluded to the frugivorous habits of the species, we need scarcely add, that the specific name is greatly misapplied. A vampire is an imaginary monster, the chief amusement of which was supposed to consist in sucking the blood of sleeping persons, and the superstition, however absurd, must have been sufficiently fearful to those who gave it credit, as many did in Poland and Hungary about a hundred years ago. Some vague allegations having been made regarding the blood-sucking propensities of certain bats, Linnæus bestowed the name of *vampyrus* on a large species found in Madagascar. This was unfortunate, as the actual blood-sucking bats inhabit South America, and belong to another group, which now forms the genus *Phyllostoma*.

The other frugivorous genera allied to Pteropus in their habits are PACHYSOMA, MACROGLOSSUS, CEPHALOTES, and HYPODERMA.

GENUS MOLOSSUS, Geoff., Cuv., Desm. Incisive teeth $\frac{2}{2}$, canine as usual, molar $\frac{4-4}{5-5}$; $= 26$. The upper incisives are of medium size, bifid, convergent, and slightly separate from the canine; the lower very small, as if pressed together in advance of the canines, and each terminated by two minute points. The upper canines are large; the under touch each other at the base, their points projecting outwards. The molars are large, and their crowns furnished with several sharp points. The head is large, the muzzle broad, the nostrils slightly projecting, opening forward, and provided with a little pad. The ears are large and united, and provided with a small tragus. No appendages to the nose. Tongue smooth. Interfemoral membrane narrow, and terminating rectangularly. Tail long, usually half enveloped at the base, the point free.

The species of this genus, of which about a dozen are known to naturalists, occur both in the Old World and the New. The majority, however, are natives of South America. We have no detailed information regarding their habits of life. In these, however, they are supposed to coincide with the bats of Europe. We suspect that even the characters of the teeth are imperfectly described. A pair of incisors in each jaw is rather an anomalous character for an insect-eating genus, and M. Temminck has stated his belief that several species have at first six in the lower jaw, of which four are successively dropped.

We shall merely in this place name the genera NYCTONOMUS of Geoffroy, of which, though one occurs in Brazil,[2] the species are characteristic of the Old World, and DYNOPS of Signor Savi, of which the typical species was some years ago discovered in the neighbourhood of Pisa.[3]

GENUS NOCTILIO, Linn., Cuv. Incisives $\frac{4}{2}$, canines as usual, molars $\frac{4-4}{4-4} = 26$. The central upper incisives are the largest; the inferior are placed in advance of the canines; the canines are very strong. The crowns of the molars are furnished with sharp tubercles. See Plate III., figure 3. The muzzle is short, inflated, cleft, and covered with warts or fleshy prominences. The nose is confounded with the lips. The ears are small, lateral, isolated; the tragus internal. The interfemoral membrane is very large and salient. The tail is of medium size, or rather short, and partly enveloped, partly free, and placed above the membrane. The claws of the hinder extremities are extremely strong.

The species are but few in number, and, as far as yet known, are natives of South America. They are sometimes denominated hare-lipped bats. The Peruvian bat of Pennant (*N. leporinus*) may be named as an example. See its cranium as above referred to.

GENUS PHYLLOSTOMA, Cuv., Geoff. Incisive teeth $\frac{4}{4}$, canine $\frac{1-1}{1-1}$, molar $\frac{5-5}{5-5}$ or $\frac{5-5}{6-6}$; $= 32$ or 34. The incisors have often the appearance of being closely pressed between the canine, the lateral being very small; the canines are frequently very large at their base. The head is large, and somewhat uniformly conic; the gape deeply cleft. The nose supports two membranous crests, the one leaf-like, the other in the form of a horse-shoe. The ears are large, naked, disunited. The tragus is internal, dentated, and growing from the margin of the auricular cavity. The eyes are very small and lateral. The tongue, capable of considerable extension, is beset at its extremity by corneous papillæ. The middle anterior toe has an additional phalanx. The tail varies in size, and is wanting in certain species. The interfemoral membrane likewise varies in its degree of development.

The singular creatures which constitute our present genus are believed to be peculiar to South America, where, however, they are distributed over a considerable extent of territory, from the Isthmus of Darien to Paraguay. The incisive teeth vary in number even in the same species, some of those in the lower jaw being frequently pushed out by the growth of the canines, and in different species the amount of molar teeth is dissimilar. The papillæ of the tongue above alluded to, in connection with tubercles symmetrically arranged around the mouth, bestow on several species a strong power of suction, which they frequently exercise to the disadvantage of their neighbours, by withdrawing the life-blood from man and beast. These are the famous *vampires*, of which various voyagers have given us such redoubtable accounts, and which are known to have almost entirely destroyed the first establishment of Europeans in the New World. Although they extirpated the cattle at Borgia, and elsewhere, they also feed on insects, after the manner of other bats, and according to Azzara do not venture to attack the cattle, unless when driven to extreme hunger by a deficiency of other food. The structure of the tongue is remarkable. It is about six times longer than broad, flattish above, rounded beneath, the surface slightly shagreened, and close to the extremity there is a peculiar cavity, the centre of which is marked by a raised point, and the circumference by eight warts.

The molar teeth of the spectre bat, or true vampire (*Vesp. spectrum*, Linn.), are of the most carnivorous character, the first being short and almost plain, the others sharp and cutting, and terminating in three or four points but it does not appear that it makes use of them while attacking the larger kinds of prey, trusting rather to its subtle and insidious tongue, for by no other means could it perforate the skin of a sleeping animal, without causing so much pain as to speedily arouse it from its slumbers. Now we know that the sleep of the victim is scarcely ever interrupted, though we cannot vouch for the fact that this is effected, as some of the older voyagers allege, by the fanning motion of the wings of the bat producing a *delicious coolness*, which renders repose the deeper, "till the sufferer awakens in eternity." There is no doubt, however, that the accounts given by Pietro Martyro, Ulloa, and Condamine, though perhaps stated with some circumstances of exaggeration, are substantially correct. They have been confirmed by Azzara, an accurate and discriminating naturalist of modern times. "The species," says that observer, alluding to the Phyllostomata, "with a leaf upon the nose, differ from the other bats, in being able to turn, when on the ground, nearly as fast as a rat, and in their fondness for sucking the blood of animals. Sometimes they will bite the crests and beards of the fowls while asleep, and suck the blood. The fowls generally die in consequence of this, as a gangrene is engendered in the wound. They bite also horses, mules, asses, and horned cattle, usually on the buttocks, shoulders, or neck, as they are better enabled to arrive at these parts from the facilities afforded by the mane or tail. Nor is man himself secure from their attacks. On this point, indeed, I am enabled to give a very faithful testimony, since I have had the ends of my toes bitten by them four times, while I was sleeping in cottages in the open country. The wounds which they inflicted, without my feeling them at the time, were circular, and rather elliptical; their diameter was trifling, and their depth so superficial as scarcely to penetrate the cutis. It was easy, also, on examination, to perceive that these wounds were made by suction, and not by puncture, as might be supposed. The blood that is drawn, in cases of this description, does not come from the veins, or from the arteries, because the wound does not extend so far, but from the capillary vessels of the skin, extracted thence, without doubt, by these bats, by the action of sucking or licking it.[1]"

[1] *Zoological Researches.*

[2] *Annales des Sciences Nat.*, Avril 1824.

[3] *Giornale dei Letterati*, No. 21, p. 230.

The species are numerous, and have been formed into sectional groups or subgenera by some recent writers,—chiefly in accordance with the presence or absence of the tail.

We must here pass over, without any special notice, the genus GLOSSOPHAGA, Geoff., which contains species allied in their habits to those last named, but distinguished by a longer, more extensile tongue, and other characters.

GENUS MEGADERMA, Geoff. Cuv. Incisive teeth $\frac{0}{4}$, canine as usual, molar $\frac{4-4}{5-5}$; $=26$. Ears very large and united. Tragus also much developed. Nose furnished with three appendages,—one erect, one horizontal or foliaceous, and a third like a horse-shoe. Tail wanting. Interfemoral membrane square. Third finger without the first phalanx. Tongue smooth and short.

The species of this genus, though few in number, are spread over a considerable extent of territory,—being found in Java, the island of Ternate, and along the coast of Senegal. We are not aware that naturalists have acquired any precise knowledge of their habits, except by induction from those of their congeners. They dwell in forests, and are remarkable for the great extent of their membranous expansions. One of their most singular organic characters consists in the absence, or at least rudimentary state of the intermaxillary bone, which of course entails with it the non-existence of the incisive teeth. It may be inferred, however, rather that the bone is small, inconspicuous, and suspended in the cartilage, than entirely wanting.

GENUS RHINOLOPHUS, Geoff. Cuv. Incisive teeth $\frac{2}{4}$, canines as usual, molars $\frac{5-5}{5-5}$; $=30$. The upper incisors are very small, separate, and frequently fall out; the lower are bilobed. The canines are of medium size,—the crowns of the molars jagged with extremely sharp points. The ears are of moderate size, lateral, and isolated. The expansion called the tragus is non-existent, or rather is replaced by an exterior lobe of the ear. The interfemoral membrane is large, and entirely envelopes the tail, which is long.

This genus includes some European species which we distinguish by the name of *horse-shoe bats*, in reference to the form of the appendage on the muzzle. They hang suspended during the day from the roof of caverns, and fly about in the evening twilight, preying on moths and other insects. We shall here name only the largest of the British species, *R. ferrum equinum*, which is well known in the south of England. (See Plate III., figure 1.) It is of a pale rufous brown colour, and its wings extend nearly fifteen inches.

GENUS NYCTERIS, Cuv. Geoff. Incisive teeth $\frac{4}{6}$, canines as usual, molars $\frac{4-4}{4-4}$; $=30$. The upper incisors are bilobed, and contiguous; the under trilobed. There is a deep longitudinal furrow down the muzzle, apparent even on the cranium, and margined, and partly covered, by a fold of the skin.

The species occur in Africa and Java, and are remarkable for the following peculiarities of structure. The nostrils are habitually closed, and require an act of volition to be put in communication with the external air, and the species, it is supposed, are thus enabled to establish themselves in subterranean chambers or other places, where their congeners would be destroyed by pestilential vapours. The skin forms as it were a sack around the body, with which it has scarcely any adherence, except at certain points, where there are some cellular attachments. At the bottom of each of the cheek pouches there is a small aperture communicating with this pervading sack, and by means of which the latter is filled and inflated with air, so that the creature becomes immersed in air, or surrounded as it were by a muff of that elastic fluid. The tail is terminated by a cartilaginous bifurcation, resembling the form of the letter T.[2]

Passing unwillingly over the genera RHINOPOMA, TAPHOZOUS, and MYOPTERIS of Geoff. St Hilaire, we reach the

GENUS VESPERTILIO of modern authors. Incisive teeth $\frac{4}{6}$, canine $\frac{1-1}{1-1}$; molar $\frac{4-4}{5-5}$ or $\frac{5-5}{6-6}$; $=32$ or 36. The upper incisors, pointed and cylindrical, are disposed in pairs; the under close together, inclined or projecting forwards, their edges bilobed. The canines are of moderate size, and do not touch each other at their base. The anterior molars are simply conical; the posterior have broad crowns beset with points; the lower ones are grooved on their sides; the upper, which are twice as broad, have crowns with an oblique edge. The nose has no membranous appendages; it is neither grooved nor furrowed, and the nostrils are destitute of opercles. The under lip is simple; the tongue smooth, not protractile. The ears, more or less extended, possess a tragus. The wings are of great proportional extent. The index finger has only one phalanx, the middle three. the annular and little finger only two. The interfemoral membrane is very large, and entirely includes the tail. The fur is soft and thick.

Feræ. Cheiroptera.

This extensive genus includes between thirty and forty species, some of which occur in every quarter of the globe, although they may be stated as rather characteristic of temperate regions. Most of the European Cheiroptera pertain to the restricted genus *Vespertilio*, such as the *V. murinus* of naturalists, recognisable by its oblong ears equalling the head in length, with their tragus semicordate. The great bat or noctule (*V. noctula*), of which the ears are shorter than the head, and triangular, and the nostrils bilobate, inhabits England (see Plate III., figure 2), as do likewise the *pipistrelle* and several others not yet discovered in the northern quarters of the island. The eared bat (*V. auritus*, Linn.), is a much more common species. It belongs to the genus *Plecotus*, Geoff. distinguished by the large ears which unite with each other at the base, above the cranium. (See Plate III., figure 7.) Altogether we have about thirteen different kinds of bat in Britain. We shall here terminate our brief view of the Vespertilionidæ; —“ Et nous devons faire observer ici,” we may add, in the words of Baron Cuvier, “ qu'il n'est point de famille qui ait besoin plus que celle des chauves-souris d'une revue faite sur nature et non par voie de compilation.” [1]

Family 2d.—GALEOPITHECIDÆ.

Fore arms and fingers not attenuated and extended as in bats, but furnished with curved claws. Lateral membrane not bare, as in the animals last named, but covered on both surfaces by close-set hair.

Genus Galeopithecus, Pallas. Incisive teeth $\frac{4}{6}$, canine $\frac{1-1}{1-1}$, molar $\frac{6-6}{5-5}$; $= 36$. Upper incisives very small, the lateral lengthened, compressed, cutting, with a small tubercle on each side at the base. Lower incisives inclined, and divided like the teeth of a comb; the intermediate being composed of eight laminæ, the second on each side of nine, the outermost of three or four (see Plate III., figure 8). The upper canines are very small, compressed, sharp-pointed, broad at the base; the lower are of larger size. The upper anterior molars resemble the canines, the posterior have their crowns beset with points. The muzzle is pointed. The ears are small and rounded; the fingers short, with a broad palm, and furnished with strong curved claws.

The animal known under the name of flying lemur (*Lemur volans*, Linn.), may be named as an example of our present genus. It is the *Galeopithecus rufus* of modern systems. (See Plate III., figure 5.) This species measures about a foot in length, and is of a greyish-red colour, varying with age. It inhabits the Moluccas and the isles of Sunda, and seems to be the only species distinctly known, though two others are named in systematic works. These animals are nocturnal, living on fruits and insects, and suspending themselves by their hind legs, after the manner of bats. Yet they differ greatly from all the latter in the form of the fore paws, and the presence of claws on all the fingers. Although an ample membrane extends from the sides of the neck to those of the tail, it is useful rather as a parachute, by enabling them to spring or descend from branch to branch, than for the purposes of a sustained or continuous flight. The hind feet are equally palmated with the anterior, and in each the claws alone are free. The membrane, moreover, differs from that of bats, in being clothed on both sides with short dense hair. The species above named is called *olek* by the natives of the Pellew islands, who hold it in great esteem as food, notwithstanding that it smells extremely like a fox. It is capable of running on the ground, and is said to climb trees like a cat.

Feræ. Insectivora.

The position of the genus Galeopithecus is, in truth, as yet but ill determined in our systems. It seems, however, improper to remove it far from the vicinity of the bats and lemurs. Some authors, indeed, combine it with the latter, as a family of the quadrumanous order; while others extend that order, so as to include within its range the whole of the cheiropterous tribes.

DIVISION II.—INSECTIVORA.

The animals comprising this division, though dissimilar to the preceding in their general form and aspect, resemble them in several particulars, especially in the conical points of the molar teeth. They are also for the most part nocturnal, and of darkling habits, and exhibit an additional analogy in their tendency to hybernation during the colder months. They are furnished with clavicles, but do not possess the extended lateral membrane of the cheiropterous genera. Their legs may be characterized as short, and their locomotive powers as somewhat defective. The mammæ, instead of being pectoral, as in the preceding tribes, are placed beneath the abdomen. The teeth vary so greatly in the different groups, that no generalities can be deduced regarding them.

Tribe 1st.

Two long incisives in front, followed by other incisives, and small canines, shorter than the molar teeth.

Genus Erinaceus, Linn. Incisive teeth $\frac{6}{6}$, canine $\frac{1-1}{1-1}$, molar $\frac{5-5}{4-4}$; $= 34$. Upper intermediate incisives very long, separate, cylindrical, directed forwards; the inferior inclined. Canines smaller than the molars. Body covered laterally and above with prickles, beneath with stiffish hairs.

The species of this genus commonly called hedgehogs, are few in number, and confined to the ancient continent. We need not describe the well known British species (*E. europæus*, see Plate III., figure 9), a timid nocturnal creature, which feeds on snails, earth-worms, and insects. It has also been accused of injuring eggs and poultry. It is easily tamed, and is nearly omnivorous in confinement. According to Pallas, it devours the cantharis or blistering beetle with impunity. It has also been said to resist large doses of prussic acid. The female, about the beginning of summer, brings forth from three to five young, which are at first blind, almost white, and nearly naked, although the germs of the prickles are observable. Both young and old pass the winter in a state of profound lethargy. The hedgehog occurs over the whole of Europe, except the extreme north.

Genus Sorex, Linn. Central incisive teeth $\frac{2}{2}$, false canines or lateral incisives $\frac{3-3}{2-2}$, or $\frac{4-4}{2-2}$, true molars $\frac{4-4}{3-3}$; 28 or 30. The central upper incisives are hooked and dentated at the base; the lower are elongated and projecting. The false canines, especially the upper, are much less than the central incisives. The molars have broad crowns beset with points, the upper being the largest, their cutting edge oblique. The head is very long, the nose lengthened and moveable. The ears are short and rounded. The eyes small but perceptible. The body is covered by fine short hair.

This genus consists of the small subterranean creatures called Shrews. The nomenclature of their teeth is a disputed point among naturalists. They are remarkable for certain odoriferous glands along their flanks, and, according to Geoffroy St Hilaire, for the non-existence of the optic nerve; yet nobody doubts that they can see. Shrews viewed generically, may be said to be cosmopolites, in so far as they are distributed over almost all the earth; and it is even said, that certain species occur both in Europe and America. They vary in their habits of life, some attaching themselves to dry situations, while others prefer moist meadows, and the margins of springs and quiet streams. They prey chiefly on insects, and are themselves often killed, but seldom eaten, by cats. However, owls make amends for this omission by swallowing them greedily. It is believed that even the European species are still but incompletely known, their extremely minute size enabling them to avoid the notice of naturalists. They are probably the smallest of all quadrupeds, at least we are inclined to presume so from the recorded dimensions of some of those recently described by Lichtenstein and Savi.

---

[1] *Règne Animal*, t. i. p. 122.

The most abundant species with us is the *Sorex araneus*, or common shrew. It measures about 2½ inches in length, without the tail, which is a third shorter than the body, and of a square form. The teeth are white, the ears naked and exposed. It is subject to a frequent epidemic in the autumn season, and presents one of the few instances we meet with, of an animal in a state of nature being found dead, without any apparent injury. The water shrew (*Sorex fodiens*) is somewhat larger than the preceding. It is of a blackish colour above, whitish beneath, the tail about a fourth less than the body in length, and compressed towards the end. The incisive teeth are red at the base, and the ears are in great measure concealed within the fur. There are many foreign species not, however, as yet distinctly characterised; and the learned antiquary Passalacqua informs us that he met with more than one species embalmed in a tomb of the Necropolis of Thebes. One of these was evidently, from its great size, and other characters, identical with *Sorex giganteus*, a species which, in the living state, occurs only in India. This is a fact interesting alike to the archæologist and the natural historian, as it leads to the belief, either that certain species of animals native to Egypt in ancient times, no longer occur in that country, or that the Egyptians derived from India some of the objects of their religious worship.

We may here name the TUPAIA of Raffles and Horsfield (*Sorex glis*, Diard., *Cladobates*, F. Cuvier), a new generic group from the Indian archipelago, of which the teeth agree with those of the Insectivora, although the habits of the species differ in this respect, that they prey like the Quadrumana among the branches of trees.[1] Their exact location in the system is therefore still somewhat doubtful.

GENUS MYGALE, Cuv. Differs from Sorex in having two very small teeth between the larger of the lower incisives, and in the upper incisives being triangular and flattened. Behind these incisives are six or seven small teeth, and four jagged molars.

Pallas and Geoffroy St Hilaire differ in their descriptions of the dentition of the species they have respectively described. These animals are of aquatic habits, dwelling in holes to which they enter under water, and then proceed upwards to dry and comfortable quarters. They feed on larvæ and worms, and, according to some authors, on the roots of the nymphæa. The fur of the Russian species (*M. Moscovita*, Geoff., *Castor moschatus*, Linn.) is much esteemed, on account of its being composed, like that of the beaver, of long silky hair, and of a softer felt beneath. It exhales a strong musky odour, which imbues the flesh of pike and other voracious fish which prey upon it. We are acquainted with only two species, that of Russia just named (extremely abundant in the environs of Woronech, where it is often entangled in the nets of the fishermen), and the *Desman* of the Pyrenees (*M. pyrenaica*). It is said that these creatures, not being torpid in winter, suffer dreadfully during that inclement season, from the freezing of the waters. Many perish from suffocation in their subterranean abodes,—these having no communication with the external air. The species last named has as yet been found only in the neighbourhood of Tarbes at the foot of the Pyrenees.

GENUS SCALOPS, Cuv. The teeth of this genus resemble those of the preceding, but their false molars are less numerous.

The only known species is the shrew mole (*S. canadensis*), a North American animal, nearly eight inches in length, with a thick cylindrical body, no apparent neck, short concealed limbs, and broad strongly nailed hands. It resembles the European mole in its habits, leading a subterranean life, forming galleries, and feeding principally on grubs and earthworms. According to Dr Godman, they exhibit the singular custom of coming to the surface daily exactly at the hour of noon, and may then be taken alive by thrusting a spade beneath them, and throwing them out of their burrows. A tame one in the possession of Mr Peale was very lively and playful, would follow the hand of its keeper by the scent (the eyes are very inefficient), and fed freely on fresh meat, whether cooked or raw. It would burrow for amusement in loose earth, and after making a small circle, would return spontaneously to its keeper. Although widely spread over North America, Dr Richardson does not think its existence probable beyond the 50th degree of latitude, at least to the eastward of the Rocky Mountains, because the earth-worm, its favourite food, is unknown in the countries of Hudson's Bay.[2]

GENUS CHRYSOCHLORIS, Cuv. Incisive teeth $\frac{2}{4}$, conical teeth $\frac{3-3}{3-3}$, molar $\frac{6-6}{5-5}$; $= 40$.

The only species distinctly ascertained to belong to our present genus, is the *C. capensis* (*Talpa asiatica*, Gmelin), commonly called the Cape Mole, an animal somewhat less than the mole of Europe, of a brownish colour, but remarkable for exhibiting (especially when moistened) beautiful metallic reflections of a green and copper colour. This burnished aspect is extremely rare among the mammiferous tribes. The species in question inhabits the Cape of Good Hope (not Siberia, as erroneously indicated by Seba), where it is found to be troublesome in gardens. It is subterranean and insectivorous, and differs from the true talpæ in having only three claws to the fore-feet.[3] Its eyes are almost obsolete. We have represented this singular animal on Plate IV., figure 2.

TRIBE 2D.

Two large upper incisors in front, followed by two others on each side, of which the first has the form of a canine; canines, properly so called, small, and not distinct from the false molars; four lower incisors inclined forwards, and spoon-shaped.

Feræ. Insectivora.

Genus Condylura, Illiger. Incisives $\frac{6}{4}$, conical teeth, or false molars $\frac{3-3}{5-5}$, true molars $\frac{4-4}{3-3}$; $= 40$.[1]

The snout in this genus is greatly prolonged, and is generally terminated by a radiated expansion, from which the name of star-nose has been applied to it. The species, of which only two or three are known to naturalists, greatly resemble moles in their manners and aspect. They have hitherto been found only in North America. We have figured the *Cond. cristata* of Desm. or "radiated mole" of Pennant. (See Plate IV., figures 1 and 1 *a*.)

Tribe 3d.

Four canines, apart,—between them small incisives.

Genus Talpa, Linn. Incisives $\frac{6}{8}$, canine $\frac{1-1}{1-1}$, molar $\frac{7-7}{6-6}$; $= 44$.

We need scarcely describe the external aspect of an animal so well known as the common mole (*T. europæa*), almost the only species of which the restricted genus *Talpa* is now composed.[2] There are few species, however, of greater interest to the naturalist, whether he regards their singular economy and instinctive habits, or their very peculiar organic structure. Moles present as it were the type or perfect form of a subterranean dweller. The snout is pointed, yet strong and flexible, the head somewhat depressed, the eyes inconspicuous, the external ears wanting, the cervical ligament unusually strong, the bones of the anterior extremity angular, and so extremely thick as to be almost as broad as they are long. The two bones of the fore-arm are fastened together, the paws are broad and shovel-shaped, with strong claws, and an elongated bone of the carpus communicates great solidity to their under edges. The clavicles are very powerful, and the motive muscles of the anterior extremity, especially the pectorals, are enormous. Although the organs of sight are feebly developed (they suffice, however, for whatever visual perceptions may be necessary to an almost constant dweller in subterranean darkness), the senses of hearing, touch, and smell, are acute.

The galleries of the mole are constructed with admirable sagacity and art, and the female brings forth in a dry and sheltered chamber, well furnished with grass and leaves. The exact period of gestation is unknown, but as young are found in spring and autumn, it is obvious that she produces twice a-year. She is careful of, and much attached to, her young; but, except in relation to these, and during the pairing season, moles lead a solitary and an isolated life. They are extremely voracious,—their appetite for food, according to Geoffroy St Hilaire, amounting to an actual phrenzy. When kept for a time in a state of abstinence they become outrageous, and will dart with violence upon whatever prey is then presented,—plunging their heads into the abdomen of birds and other animals, and satiating themselves with blood. They have been observed to refuse toads, but to seize upon frogs with avidity. With such violent propensities it may be easily conceived that they soon die of famine when debarred from food. At the same time their appetites are not so entirely carnivorous; at least several authors allege that they occasionally eat various tender and succulent roots, and the bulbs of the *colchicum*. Though deemed very injurious in gardens, and persecuted by farmers even in the open grounds, they do not want advocates who espouse their cause as useful agents in the general economy of nature; and their undoubted destruction of grubs and mole-crickets must prove beneficial to agriculture. The female, indeed, while furnishing her nursery, is a somewhat too active reaper,—402 young stalks of corn, with the leaves entire, have been counted in her nuptial chamber.

The existence of the optic nerve in moles is a greatly contested point among physiological naturalists. Durandeau and Dr Gall, conceiving vision to be impossible in the absence of that nerve, presumed it to exist in those animals in a complete and normal condition. Carus, Bailly, and Treviranus, have sought to establish its existence in a rudimentary state; while its total absence is maintained by Serres and Desmoulins. Geoffroy St Hilaire presumes himself to have reconciled these various opinions with the truth of nature, by shewing that, although the optic nerve does not occur under the same conditions as it exhibits among the normal quadrupeds, its analogue is found in a branch which proceeds from the eye to the fifth pair. Ancient writers have been accused of inaccuracy, in describing the mole as blind; and this would certainly have been a gross error in relation to an animal, of which the eyes, though small, are so distinctly perceptible. It is true that Aristotle twice repeats the assertion that the mole has no eyes; but we must remember that the true mole is extremely rare in Greece, and that the ασπαλαξ of the ancients (translated mole) is another animal (*Aspalax typhlus*), of which the eyes are in truth entirely covered by the skin. It is only in comparatively recent times that naturalists have become acquainted with a species, the remarkable conformation of which thus excuses, if it does not verify, the statement of the Stagyrite.

The only other mole found in Europe is one discovered among the Apennines by Signor Savi. It is said to be entirely blind, and has, in that belief, been named *Talpa cæca* by the Italian naturalist.[3] It is somewhat less than the common species, and one of our correspondents states his belief that it occurs in France.

Genus Centenes, Illiger. Incisives $\frac{6}{6}$ or $\frac{4}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{6-6}{6-6}$; $= 40$ or 38.

The species of this genus resemble hedgehogs in the prickles which are intermingled with their hair, but their teeth are very different. They are nocturnal animals, and inhabitants of the torrid zone (occurring in Madagascar and the Isle of France), and are said to pass several months of the year in a lethargic state. This is a singular circumstance in the history of any intertropical species; and the term hybernation, usually bestowed upon the torpid condition (in consequence of its constant connection with the cold of winter), cannot be used in the present instance, because, according to the relation of Bruguiere, it most frequently occurs during the greatest heats. About three species of the genus are known to naturalists. As an example, we have figured the radiated Tanrec (*Centenes semi-spinosus*), which is no larger than a mole (See Plate III., figure 10.) The tanrecs are known to Europeans under the title of pig-porcupines. They utter a grunting cry, are generally very fat, and are used as food by the natives of Madagascar.

---

[1] The student who finds a discrepancy in our statement of the above dentition (or in that of other insectivorous groups), when compared with the descriptions of other authors, will bear in mind that this arises chiefly from a difference in nomenclature. In the present instance we follow M. Desmarest. Baron Cuvier seems to think that in *Condylura* there are only two pair of incisive teeth in the upper jaw; what we have considered as the third pair, being regarded by him as the canines. We presume the place of their insertion in relation to the maxillary bone would determine the point; but we have ourselves no access to a cranium of any species of the genus.

[2] Bartram and other writers who have asserted the existence of moles in America, are supposed by later writers to have mistaken the shrew-mole (*scalops*). Sir J. Richardson, however, informs us that there are several true moles in the Museum of the Zoological Society, which were brought from America. They differ from the common European species in being smaller in size, with a thicker and shorter snout. The fur is brownish-black. Dr Harlan supposes the mole of the United States synonymous with *T. europæa* of Linn. It was named *T. americana* in Dr Bartram's MS.

[3] *Memoire Scientifiche, decade prima.* Consult also C. L. Bonaparte's *Iconografia della Fauna Italica.*

DIVISION III.—CARNIVORA.

The genera of this division are characterized by possessing six incisors in each jaw. Their molars are usually of a trenchant or cutting character, sometimes tuberculous, but never beset with the jagged points which we so often meet with in the preceding division. Their canines are extremely strong.

Although the epithet carnivorous, as Baron Cuvier has remarked, applies, in a considerable degree, to all unguiculated quadrupeds which possess the three different kinds of teeth, since the whole are more or less dependent on animal matter for their support, yet it is among the various groups of our present division that we meet with the really sanguinary kinds. They are more or less exclusively carnivorous, according as their teeth are more or less of a cutting character, and their regimen might almost be calculated from the relative proportion between the tubercular and the cutting surface of their grinders. The bear tribe, which is the best adapted (of carnivorous creatures) for subsisting on a vegetable diet, has almost all the teeth tubercular. Hence the accordance of its love for fruits and berries.

The anterior molars of this division are usually the sharpest on their edges; then follows a molar larger than the others, and usually furnished with a tubercular heel. Behind that molar we find one or two small teeth nearly flat upon the crown. It is with these latter that dogs chew the grass which they so frequently swallow. The great molar just alluded to, and the corresponding tooth of the upper jaw, are what we designate as the carnivorous cheek-teeth (*les carnassieres* of F. Cuvier); the anterior pointed ones are the false molars, and the flattened posterior ones, the tubercular grinders. The amount of these teeth differs slightly in some of the genera. Thus, for example, in the feline race, or cats, there is no separate tubercular tooth in the lower jaw; but its function is performed by the inner projecting lobe of the under carnivorous cheek-tooth, the rounded point of which, when the jaws are closed, is applied to the flat surface of the upper tubercular grinder. It will be readily conceived that such species as possess the fewest false molars, and the shortest jaws, have the greatest power in biting, and are likely to prove the most carnivorous.

We subdivide the CARNIVORA, in the first place, into three principal tribes, in accordance chiefly with certain distinctive peculiarities in the form of the hinder feet. These tribes are named PLANTIGRADA, DIGITIGRADA, and PINNIPEDIA.

TRIBE I.—PLANTIGRADA.

Entire sole of the foot placed upon the ground in walking. Five toes to both the fore and hind extremities. No cæcum.

GENUS URSUS. Linn. Incisors $\frac{6}{6}$, canine $\frac{1-1}{1-1}$, molar $\frac{6-6}{7-7}$; $=42$. Tail short.

Of the six molars on each side of the upper jaw of this genus there are three which we would denominate false molars; another corresponds to the carnivorous cheek-tooth, and the remaining two are tuberculated grinders. In the under jaw there is generally an additional molar on each side. It must be remembered, however, that the number of teeth in the bears is very variable even in the same species, according to the age of the individual. The false molars especially vary greatly,—for in young animals they have not become apparent,—in aged ones they have disappeared.

Among carnivorous quadrupeds, as we have already hinted, we find many different degrees of ferocity, from the all-subduing and blood-thirsty disposition of the tiger, which so savagely rejoices to imbrue its horrid jaws in the palpitating flesh of a living victim, to the more omnivorous propensities of the Plantigrada, such as the bear, racoon, or coati-mundi,—species which, though addicted to prey on other animals, are at the same time endowed with a much greater capacity to adapt their constitution to a miscellaneous diet. This accommodating instinct no doubt corresponds with, if it does not proceed from, the less determinate formation of the digestive and prehensile organs; such as the stomach, teeth, and claws. The unequalled strength and activity of the tiger,—its sharp retractile talons, the great development of the canine teeth, and the compressed and cutting character of the molars, combined with the simplicity of the stomach, and the shortness of the intestinal canal, render it, as it were, the type of carnivorous animals. It exhibits no tendency in any of its forms to the herbivorous structure, but is strictly and characteristically a flesh-eating animal, "a most beautiful and cruel beast of prey." It is otherwise with our present genus, containing the race of bears. Their external forms are massy and inactive, their claws are unretractile, their muzzles more elongated, their jaws consequently weaker, and their teeth, though sufficiently formidable, manifest a decided relation to the herbivorous structure in the breadth of the molars, and their bluntly tuberculated crowns. In accordance with these conditions of their organization, we find that even the polar bear (*Ursus maritimus*), one of the most carnivorous of its kind, may be sustained for a length of time in captivity, on bread alone. It is known that several species, in the wild state, are remarkably fond of honey (a substance which, though in one sense an animal secretion, is, in another and more essential one, a vegetable product), and have been observed climbing trees to obtain it. Others feed on fruits, reptiles, insects, particularly ants; and Sir Stamford Raffles possessed a tame Malay bear (*U. Malayanus*), which gave proof of its refined appetite, by refusing to eat any thing but mangosteens, or to drink any other wine than champagne.[1]

Here, then, as among every other group which can occupy the attention of the naturalist, we find the most beautiful and harmonious uniformity to prevail between the special end in view, and the means of its attainment. Of all carnivorous animals, bears are the least qualified either to pursue in open warfare, or to secure by ambuscade, a living prey. Their plantigrade position renders their movements comparatively slow, and the nearly equal length of their fore and hind legs deprives them of the power of leaping. Had, therefore, their natural love of flesh and blood been as insatiable as that of the tiger, and their means of obtaining it so much more restricted, their lives must have passed in misery, and the species would ere long have become extinct.[2] But HE who "tempers the wind to the shorn lamb," has drawn strength from this very weakness, and ordained that, with the deterioration of those characters which are essential to the well-being of a strictly carnivorous animal, should arise a capacity of deriving nourishment from a wider and more miscellaneous range of materials,—and thus the balance is beautifully maintained between the instinctive propensity and the subduing power.

---

[1] *Linn. Trans.* vol. xii.

[2] Wilson's *Illustrations of Zoology*, vol. i. Genus Ursus.

The geographical distribution of the genus *Ursus*, though formerly believed to be confined to northern countries, is now known to be very extensive. We are acquainted with eight or nine species, several of which occur in the warmer regions of Continental Asia, and the Indian Islands. We cannot here, however, afford room for more than the briefest summary. The white or polar bear (*U. maritimus*), which does not occur among the antarctic icebergs, is common to the northern shores of Asia and America. This gigantic prowler among frost-bound regions, attains to a higher latitude than any other known quadruped, and seems indeed to dwell by preference

> "In thrilling regions of thick-ribbed ice."

Its southern limit seems to be somewhere about the 55th parallel. It is a truly ice-haunting and maritime species, occurring along a vast extent of shore, but never entering into wooded countries, except by inadvertence, or during the prevalence of great mists, nor shewing itself, unless accidentally, at any considerable distance from the sea.[1]

It might naturally be supposed, that animals of almost gigantic size, of great strength, and considerable ferocity, would be too formidable and dangerous to the human race, to remain long unknown in any of their distinguishing characteristics. Yet the specific differences, it must be admitted, of the black and brown bears, both of Europe and America, are still insufficiently illustrated. Both continents produce a black bear and a brown one; the white or polar species, just mentioned, is common to the northern latitudes of each, while America alone is inhabited by the grizzly bear, *Ursus ferox*. This is undoubtedly the most formidable animal of the northern parts of the New World. When full grown it equals in size the great polar species, and is not only of more active habits, but of a fiercer and more vindictive disposition. Its strength is so enormous, that it will drag away the carcass of a buffalo weighing a thousand pounds. Dr Richardson informs us, that a party of voyagers, who had been occupied all day in tracking a canoe up the Saskatchewan, were seated around a fire enjoying the repose of the evening twilight, and partly occupied in the agreeable task of preparing their supper. Suddenly a huge grizzly bear sprung over the canoe, which they had tilted behind them, and seizing one of the party by the shoulder, carried him off. The remainder were scattered in terror, with the sole exception of a *metif* named Bourasso, who, grasping his gun, followed the bear, whom he saw deliberately retreating with his companion in his mouth. He called out to his unfortunate comrade that he was afraid to fire lest he should hit him instead of the bear, but he was answered to fire instantly, as the monster was *squeezing him to death*. On this he took steady aim, and lodged his ball in the body of the brute, which immediately dropped its original prey, and turned round to revenge itself upon the brave Bourasso. He, however, contrived to effect his escape, and the bear, probably feeling itself severely wounded, disappeared into a neighbouring thicket. The rescued man eventually recovered, although one of his arms was fractured, and he was otherwise severely bitten. Another individual, still living in the neighbourhood of Edmonton House, was attacked by a bear of this species, which suddenly sprung out of a thicket, and *scalped* him by a single scratch of its tremendous claws, laying bare the skull, and pulling down the skin of the forehead quite over the eyes. Assistance being at hand, he was rescued from the bear without farther injury, but he was left in a painful and unfortunate predicament, for the scalp not being properly replaced in time, he lost the power of vision (although his eyes remained uninjured), owing to the hardening of that skinny and tenacious veil.[2] The grizzly bear inhabits the Rocky Mountains, and their eastern plains, at least as far north as latitude 61°, and its southern range, according to Lieutenant Pike, extends to Mexico.[3]

Another and much smaller species of the New World is the black bear of North America (*U. Americanus*, see Plate IV., figure 3). It is esteemed as food. The only South American species with which we are acquainted, is the *Ursus ornatus* of Frederick Cuvier (*Ibid.* figs. 4 and 4 *a*). It is black, with the throat and muzzle white, and a large fulvous spot upon the brows. The European bears are generally supposed to be two in number, the brown or common bear (*U. arctos*, Linn.), and the black bear (*U. niger*). The latter, however, is by some considered only as a variety. There are at least three bears in India. The long-lipped bear (*U. labiatus*) is met with occasionally in menageries in this country, under the name of Ursine Sloth (first bestowed upon an individual accidentally deficient in the canine teeth). It dwells in holes and caverns, which it sometimes excavates with its long claws, and feeds on fruit, insects, and honey. It is rather a docile and intelligent animal, and is taught various tricks by the jugglers of Bengal, who frequently exhibit it for the amusement of the people. The Malay bear (*U. Malayanus*, Raffles), before alluded to, occurs likewise in Sumatra, where it is said to cause great damage by climbing to the summit of the cocoa trees to drink the milk, after devouring the tops of the plant. A third Indian species is the bear of Thibet (*U. Tibetanus*, Cuv.), a species intermediate between the two preceding, but more ferocious than either. Its claws are weaker than usual, and some suppose that it cannot climb trees. It was found by Dr Wallich among the mountains of Nepaul, and by M. A. Duvaucel in those of Silhet. We may conclude by observing, that bears have never been found in any part of Africa in modern times, although those of Lybia are mentioned by Virgil and other ancients:—

> Acestes
> Horridus in jaculis et pelle Libystidis ursæ.

GENUS PROCYON, Storr., Cuv. Incisors $\frac{6}{6}$, canine $\frac{1-1}{1-1}$, molar $\frac{6-6}{6-6}$; $=40$. Tail long. Six ventral mammæ.

This genus contains the animals commonly called racoons. We have no precise knowledge of more than two species. The first is the common racoon of North America (*P. lotor*, Cuv. *Ursus lotor*, Linn.), a fox-like creature, with the gait of a bear. In a state of nature it sleeps throughout the day, prowling during the night in search of fruits, roots, birds, eggs, and insects. At low water it frequents the sea-shore, where it preys on crustacea and shell-fish. It climbs trees with great facility. According to M. Desmarest it extends as far south as Paraguay. But it is the second species or crab-eating racoon (*P. cancrivorus*, Geoff.), which is the more characteristic of the southern portion of the New World.

The genus AILURUS of Fred. Cuvier, may be here mentioned as allied to the racoons. It possesses, however, only one false molar instead of three. Its dentition is not distinctly known. One species only has been hitherto recognised, the *A. fulgens*, a native of the mountains of Northern India.[1] It is an extremely beautiful animal, clothed in a soft dense fur, the upper parts of a bright cinnamon red, the under surface deep black. In size it resembles a large domestic cat, and dwells by preference among trees in the vicinity of streams and torrents, preying on birds and small quadrupeds. It offers in some measure a combination of the characters of the bears, civets, and racoons. (See Plate IV., figures 6 and 6 *a*.)

---

[1] The student who desires to complete his knowledge of this interesting animal, is referred to Martin's *Voyage to Spitzbergen*, Fabricius's *Fauna Grœnlandica*, Pennant's *Arctic Zoology*, Scoresby's *Account of the Arctic Regions*, the *Appendix* to Parry's *Second Voyage*, and Richardson's *Fauna Boreali-Americana*, part 1st. The same works may of course be consulted with equal advantage for the history and description of other arctic quadrupeds.

[2] *Fauna Boreali-Americana*, part 1st, p. 27.

[3] *Travels on the Missouri and Arkansaw.*

Another recently constructed genus is named ICTIDES, by M. Valenciennes.[2] The three hindermost molars of the upper jaw are much smaller and less tuberculated than those of the racoons, especially the farthest back in each jaw, which is very small and almost simple. (See Plate IV., figure 5.) The tail is long and densely furred, with an involved appearance as if it were prehensile. Two species have been described,—*Ict. albifrons*, a native of Sumatra, Malacca, and Java; and *Ict. ater*, found chiefly in Malacca. They are not yet distinctly characterized or discriminated, and one or other of them is the *Binturong* of Raffles.[3] It was observed to climb trees, with the assistance of its tail, which has uncommon strength. Major Farquhar kept one alive for many years. It fed both on animal and vegetable food, was particularly fond of plantains, but also ate readily of fowl's heads, eggs, &c. It was most active during the night.[4]

GENUS NASUA, Storr., Cuv. Incisors $\frac{6}{6}$, canine $\frac{1-1}{1-1}$, molars $\frac{6-6}{6-6}$; = 40. Tail long, covered with hair, not prehensile. Six ventral mammæ. No cæcum.

This genus contains the well-known South American animals called *coatis*, or *coati mondis*, so frequently seen in our menageries. Individuals vary greatly in colour, and it is the impression of some observers, that the red and brown coatis, *N. rufa* and *fusca* (*Viverra nasua* and *nasica* of Linn.), are identical. We have represented the so called *Nasua rufa* on Plate IV., figure 7. In a state of nature these animals dwell in the woods, preying on such small birds and quadrupeds as they can overcome, and producing occasional devastation in sugar-cane plantations. They are often domesticated in Brazil, Guiana, and Paraguay, but it is necessary to keep them chained, as they climb better than cats, and are always getting into mischief, from their restless activity and habits (otherwise praiseworthy) of general inquiry, which induce them to poke their snouts into every unaccustomed hole and corner. A specimen at present in our possession is extremely domestic, much attached to society, and also very fond of strawberries, earthworms, honey, eggs, chickens (either raw or roasted), young frogs, and green pease.

We may here allude briefly to the genus POTOS of Geoffroy (*Cercoleptes*, Illiger), which contains only a single species of a somewhat anomalous aspect. It is the *yellow maucoco* of Pennant (*P. caudivolvulus*, Desm.), frequently called the *kinkajou*. Its size is nearly that of a domestic cat, and its physiognomy is remarkably like a lemur's. A tame one kept by F. Cuvier was mild and fond of caresses. It loved obscurity, and slept much during the day. It occasionally ate meat, but preferred a vegetable diet. It was a dexterous climber. According to Humboldt it is very abundant in New Grenada, and was among the number of those animals formerly reduced by the aborigines to a domestic state. It is said to be a great destroyer of the nests of wild bees, and makes use of its long tongue to extract their gathered sweets. On this account it was named the *honey bear*, by the missionaries.

GENUS MELES, Storr. Incisives $\frac{6}{6}$, canine $\frac{1-1}{1-1}$, molars $\frac{5-5}{6-6}$; = 38. Tail very short. Two pectoral and four ventral mammæ. An anal pouch.

Here naturalists place the badgers, a small genus, widely distributed over Europe, and occurring both in Asia and America. At the same time we have no precise knowledge of more than two species. Our common badger (*Meles vulgaris, Ursus meles*, Linn.) is greyish-brown above, beneath black, with a longitudinal black band on each side of the head, passing round the eye and ear. The tuberculous molars at the bottom of each jaw, especially those of the upper, are distinguished by their extent, of which the effect is to limit that of the carnivorous teeth, and consequently to diminish the natural appetite for flesh, or, at all events, the power of exercising it. The tuberculous molar of the upper jaw, occupies a space equal to that of the carnivorous cheek tooth, and of the two false molars, by which it is preceded, and the lower half of the under carnivorous tooth is enlarged, so as to be properly opposed to the larger tuberculous tooth above. It is thus half tuberculous and half carnivorous. The second incisives of each side of the lower jaw are not inserted on the same line as the others, but farther in. Although the badger is undoubtedly a carnivorous animal, it is much less so than many others of the ferine order, and even in a state of nature feeds freely on fruits and roots. We have known it enter a garden to devour strawberries. When domesticated it is omnivorous, like the cat and dog. Its subterranean life, and woodland habits, are well known.

The American badger (*Meles Labradoria* of Richardson and others), or *carcajou* of Buffon, is of a mottled or hoary grey colour above, whitish on the under surface. The fur is very soft and fine. This species inhabits the sandy plains or prairies which skirt the Rocky Mountains as far north as the banks of the Peace River. It abounds in the plains of the Missouri, although its southern range has not been hitherto defined. The holes which it perforates in the prairies, in the vicinity of Carlton-house, are often annoying to horsemen, especially when the ground is covered with snow. The greater number of these burrows, however, are not dug by the badger itself, but are merely enlargements of the subterranean dwellings of marmots (*Arctomys Hoodii* and *Richardsonii*), which it at the same time most ungenerously digs up and devours. It appears indeed to be fully more carnivorous than the European species,—a specimen which Sir J. Richardson killed, having had a small marmot nearly entire, and several field mice, in its interior. But it had also been feeding on some vegetable matter. It passes the winter, from November to April, in a torpid state.[5]

Although the badgers approach the marten tribe in the characters of their dentition, they are far from resembling those finely formed, light, and lively creatures in other particulars; their bodies, though strong and muscular, being rather heavily formed, and their movements by no means active. Their physiognomy, it has been observed, announces neither quickness of intelligence, nor vivacity of passion. They lead a retired, if not a solitary life. Badgers, though frequently mentioned by Latin writers under the names of *taxus* and *meles*, seem to have passed unnoticed by the Greeks. Yet we know that the European species occurs in Calabria.

[2] *Annales des Sciences Nat.* t. iv.

[3] The species have even been commingled by several recent systematic writers with the genus *Paradoxurus*.

[4] *Linn. Trans.* vol. xiii. p. 254.

[5] *Fauna Boreali-Americana*, Part i. p. 39.

GENUS GULO. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{5-5}{6-6}$, or $\frac{4-4}{6-6}$; $=$ 38 or 36. No anal pouch.

The Glutton of the north of Europe (*Gulo arcticus*, *Ursus gulo*, Linn.) may be mentioned as an example of our present genus. It is common in Norway, especially in the neighbourhood of Drontheim, and is remarkable for its fierceness and voracity. It is said to climb trees, that it may the more readily pounce upon deer and other large animals which it could not otherwise obtain. It fastens on their necks with teeth and claws, till its astounded prey rolls upon the earth from loss of blood, or terror at such an unexpected and insidious foe. In a domestic state it has been known to eat thirteen pounds of flesh in a single day. It is not larger than a badger. The glutton does not become torpid in the winter season.

The Wolverine of North America (*Gulo luseus*, Sabine), though regarded by Baron Cuvier as nothing more than a variety of the preceding, is by others considered as a well distinguished species. Its habits are characteristically described by Sir J. Richardson: "The Wolverine is a carnivorous animal, which feeds chiefly upon the carcasses of beasts that have been killed by accident. It has great strength, and annoys the natives by destroying their hoards of provision, and demolishing their marten traps. It is so suspicious, that it will rarely enter a trap itself, but, beginning behind, pulls it to pieces, scatters the logs of which it is built, and then carries off the bait. It feeds also on meadow-mice, marmots, and other *rodentia*, and occasionally on disabled quadrupeds of a larger size. I have seen one chasing an American hare, which was at the same time harassed by a snowy owl. It resembles the bear in its gait, and is not fleet; but it is very industrious, and no doubt feeds well, as it is generally fat. It is much abroad in the winter, and the track of its journey in a single night may be often traced for many miles. From the shortness of its legs, its makes its way through loose snow with difficulty, but when it falls upon the beaten track of a marten trapper, it will pursue it for a long way. Mr Graham observes, 'that the Wolverines are extremely mischievous, and do more damage to the small fur trade, than all the other rapacious animals conjointly. They will follow the marten hunter's path round a line of traps extending forty, fifty, or sixty miles, and render the whole unserviceable, merely to come at the baits, which are generally the head of a partridge, or a bit of dried venison. They are not fond of the martens themselves, but never fail of tearing them in pieces, or of burying them in the snow by the side of the path, at a considerable distance from the trap. Drifts of snow often conceal the repositories thus made of the martens from the hunter, in which case they furnish a regale to the hungry fox, whose sagacious nostril guides him unerringly to the spot. Two or three foxes are often seen following a wolverine for this purpose.'[1] The wolverine is said to be a great destroyer of beavers, but it must be only in the summer, when those industrious animals are at work on land, that it can surprise them. An attempt to break open their house in the winter, even supposing it possible for the claws of a wolverine to penetrate the thick mud walls when frozen as hard as stone, would only have the effect of driving the beavers into the water to seek for shelter in their vaults on the borders of the dam."[2] Next to the polar bear, the wolverine is one of the most northern of known quadrupeds. Its bones were found in Melville Island, nearly in latitude 75°.

A third species of this genus is the Grison, or banded glutton (*G. vittatus*), an inhabitant of a warmer clime. It is very common in Paraguay. A fourth is the Taira (*G. barbatus*,—*Mustelus barbatus*, Linn.), described by Azara under the name of *le grand furet*. It is likewise a native of South America.

The *Ratel*, or cape glutton (*G. mellivorus*,—*Viverra mellivora* and *capensis*, Gmelin), differs from the preceding in having one false molar less in each jaw, and in the upper tubercular teeth being slightly developed, as in cats; but in its external aspect it resembles the grison and badger. It is described by Sparmann as being about the size of the latter,—the fur greyish above, and black below, with an intermediate line of white. It inhabits the Cape of Good Hope, where, with its long claws, it disinters the nests of wild bees, and feeds upon their honey. Though long regarded as exclusively of African origin, it now appears, on the testimony of General Hardwick, to occur in several parts of India, along the courses of the Ganges and the Jumna. Its manners, however, do not at all correspond with those assigned to the African variety. It inhabits the high banks of the great rivers, and seldom issues abroad during the day. At night it prowls about the Mahommedan habitations, and will sometimes even scratch up recently interred human bodies, unless the graves be protected by a covering of thorny shrubs. So rapid indeed are its subterranean operations, that it will work its way beneath the surface in the course of ten minutes. Its favourite food consists of birds and small quadrupeds. There is a specimen of this animal in the London Zoological Gardens, remarkable for its playfulness and good humour. It solicits attention by a great variety of postures, and tumbles head over heels as soon as it has succeeded in attracting the notice of a visitor.[3]

TRIBE II.—DIGITIGRADA.

The groups of this tribe derive their name from their peculiar mode of locomotion. The heel does not touch the ground, and the act of walking is performed, as it were, upon the toes. We may name as familiar examples the pole-cats, martens, dogs, hyenas, and the whole of the feline race. Like most of our attempts, however, at a general arrangement, founded on any single attribute, we find this principle imperfect, or at least admitting of exceptions in relation to the character prescribed, in as far as several species might be adduced, which truly agree with their digitigrade congeners in their prevailing character, but approach the plantigrades in their mode of locomotion.

The genuine *Digitigrades*, however, such as cats, are among the most agile of their tribe, and as activity is an almost indispensable adjunct in the habits of a carnivorous creature, we find that these light-footed kinds are also the most exclusively flesh-eating of all the ferine order. Indeed all the genera of our present tribe may be said to be more strictly carnivorous than those of the preceding.

1ST SUBDIVISION.

A single tuberculous tooth behind the carnivorous cheek-tooth of the upper jaw. Body much elongated. Limbs short.

This subdivision corresponds to the old genus MUSTELA of Linnæus, and includes all those small and slender bodied animals which, in our own country, are usually designated as *vermin*, such as weasels, polecats, &c., the *Verminium genus* of Ray. They are very blood-thirsty, and extremely destructive for their size, destroying great quantities of game, both in woods, fields, and moorish mountains, and committing ravages in poultry-yards, and other enclosures, especially of remote country dwellings. They are wary, nocturnal, and insidious, and, from their worm-like form, can penetrate minute openings,—thus gaining access to places where their presence was little expected, and less desired. The general dentition may be stated as: incisives $\frac{6}{6}$, canine $\frac{1-1}{1-1}$, molars $\frac{4-4}{5-5}$ or $\frac{5-5}{6-6}$; = 34 or 38.

---

[1] Graham's *MSS.* p. 13.

[2] *Fauna Boreali-Americana*, Part i. p. 43.

[3] *Gardens and Menagerie*, vol. i. p. 20.

We shall now proceed to give a short sketch of the minor genera (increased in number though restricted in extent), into which the musteline group of Linnæus has been subdivided in recent times.

The polecats (subgenus *Putorius*, Cuv.[1]) are among the most sanguinary. Their lower carnivorous cheek-tooth has no interior tubercle, their upper tubercular tooth is broader than long, and they have only two false molars above and three below, on each side. They exhale a strong and disagreeable odour. The species are extremely numerous, and widely spread. We have three well known British kinds,—the foumart, or common polecat (*M. putorius*, Linn.), of which the ferret (*M. furo*) is regarded simply as a variety by some,—the weasel (*M. vulgaris*, Linn.), and the ermine or stoat (*M. erminea*, Linn.). Another species, remarkable for its amphibious habits, and known under the name of *Mink* (*Mustela lutreola*, Pallas), is very common in Finland, and in other parts of the north and east of Europe, from the Icy to the Black Sea. Erxleben, however, is in error when he supposes it to be a North American species. The animal of the New World is the vison (*M. vison*, Gmelin) or minx otter of Pennant.[2] Both species prey much on fish, reptiles, and aquatic insects, and the latter is easily tamed. "One," says Sir J. Richardson, "which I saw in the possession of a Canadian woman, passed the day in her pocket, looking out occasionally, when its attention was roused by any unusual noise."[3] Other species inhabit the warmer countries of the earth, such as Africa (*P. africanus*, Desm.), Madagascar (*P. striatus*, F. Cuvier), and Java (*P. nudipes*, Id.). The last-named animal, of a yellowish fawn-colour, with the head and termination of the tail white, is figured in this work, Plate V., figure 1. There is a Cape species (*Viverra zorilla*, Gmelin) which, in its general aspect, resembles the polecats; yet the form of its fore-claws is somewhat peculiar, and seems to indicate subterranean habits of life, and a propensity to dig. It has, on this account, been formed by some authors into a separate subgenus under the name of *Zorilla*,—perhaps an inappropriate title, and apt to mislead the student, in as far as it was first applied by Spanish writers to one of the mephitic species of America.

The Martens properly so called (MUSTELA of Cuvier, but to which the generic name of MARTES would be more appropriately applied), have a small interior tubercle on the lower carnivorous cheek-tooth, and (compared with the preceding) an additional false molar both above and below. Each of these characters is supposed to indicate some diminution of the purely carnivorous propensity. We have two British species, the common or beech marten (*M. fagorum*, Ray, *M. martes*, var. *fagorum*, Linn.), of which the throat and breast are white, and the pine marten (*M. abietum*, Ray, *M. martes*, var. *abietum*, Linn.), of which the throat and breast are dingy yellow. The former is the more common in England, and the southern and central parts of Scotland,—the latter prevails in the north. Though the specific names are derived from their supposed propensities towards particular kinds of forests, it appears that their habits, like those of most other species, are of an accommodating kind. Both sorts, and more especially the first named, are often found in districts "rocky, bare, sublime," of which the most hopeless attribute is that of forest scenery. The common marten more frequently approaches farm-houses than the other, and was probably, for that reason, distinguished by the name of *domestica* by the old writers, such as Gesner and Aldrovandus. The pine marten is extremely common over the northern parts of America, from the Atlantic to the Pacific, and is particularly abundant where the trees have remained standing after being killed by fire. Its fur is fine, and has long formed an important article of commerce, upwards of a hundred thousand skins being collected annually in the districts devoted to the trade. It is well known that it also formed a lucrative subject of export from Scotland before the Union. Dr Fleming says it builds its nest on the tops of trees. According to Sir J. Richardson, its habits in America are rather subterraneous. We have seen its young winding their worm-like way amid the treeless *corries* of the Highland mountains, where not even a sapling wild-ash waved its leaves in the grey solitude.

One of the most famous of the foreign martens is the zibelline or sable (*M. Zibellina*, Linn.), so noted for the beauty of its fur. It is very like our martens both in size and proportions, and is usually of a rich lustrous brown colour, somewhat paler in summer, and marked during that season with grey upon the throat, and whitish on the ears and face. It is spread over a wide extent of northern Asia, where it is held in the highest estimation of all the fur-bearing animals; and its pursuit among the frozen wastes of Siberia and Kamtschatka is probably the most painful as well as perilous of those sacrifices which the human race, either by force or free will, have ever made to the love of riches. The winter robe is by much the most esteemed, being then fuller, darker, softer, and more flexible and lustrous than at any other season. In this state it is equally coveted by Chinese mandarins, Tartarian chiefs, and the noblesse of Europe, and is justly regarded as one of the most precious and magnificent of all the artificial adornments of the human frame. A single skin of the richest quality is worth from twelve to fourteen pounds, and in its attempted acquisition many hardy hunters perish miserably of cold and famine. The Russian dealers, however, are so skilful in the perfect preparation of these furs, that they often succeed in selling the summer skins for those of winter. We may add, that to the pursuit of the sable we owe the discovery of the eastern countries of Siberia.

The pekan or fisher (*M. canadensis*, Linn.) is a well known species of North America. Its habits resemble those of the pine marten, but it is nearly twice the size, and its fur is coarser, and less valuable.

GENUS MEPHITIS, Cuv. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{4-4}{5-5}$; = 34. As in the polecats, there are two false molars above and three below, but the upper tubercular tooth is very large, and as long as broad; the lower carnivorous cheek tooth has two tubercles on its inner side, a character in which the species approach the badgers. They resemble the latter also in the lengthened claws of the fore feet, and the almost plantigrade form of the hinder extremities.

---

[1] Baron Cuvier has applied the generic name *Putorius* to the group which contains the polecat and the weasel, and he bestows that of *Mustela* on the martens. We think the latter should have been given to whatever group contained the true weasel (*M. vulgaris*, Linn). as it is otherwise apt to carry false associations. Some recent writers adopt the genus *Putorius*, as assigned by Cuvier, but give the title of *Martes* to the martens properly so called. This is very well in its way, but then we lose the term *mustela* altogether as a generic appellation. Now we think, that whenever a Linnæan genus is raised to the rank of a family, the original generic title should still be retained, as indicative of one of the restricted groups.

[2] *Arctic Zoology*, vol. i. p. 87, and *Fauna Boreali-Americana*, Part i. p. 48.

[3] *Ibid.* p. 49.

The animals of this genus are commonly called skunks or mephitic weasels, and are remarkable for their intense and ineradicable odour. Although several species are described by naturalists, it does not clearly appear that more exists than one, the skunk weasel of Pennant (*Mephitis Americana*, Rich., *Viverra putorius*, Gmelin), which is spread over a great extent of territory in the New World, and varies in different localities. Its size is that of a domestic cat, its fur, though rather coarse, is very ample, of a black colour, marked by longitudinal bands of white, and the tail, which is long and bushy, has generally two broad longitudinal white stripes above upon a black ground. The skunk, as described by Sir J. Richardson, inhabits rocky and woody regions, spending the winter in a hole, and seldom stirring abroad during the colder seasons. It preys on mice, and in summer feeds much on frogs. Its gait is slow, and it can be easily overtaken by its pursuers, as it makes no great efforts to escape by flight, but trusts the discomfiture of its enemies to the discharge of a most noisome fluid. This fluid, which is of a deep yellow colour, is contained in a small bag placed at the root of the tail, and emits probably the most overpowering stench in the known world. It is so durable, that wherever a skunk has been killed, the place retains a taint for many days. "Mr Graham says that he knew several Indians who had lost their eyesight in consequence of inflammation, produced by this fluid having been thrown into them by the animal, which has the power of ejecting it to the distance of upwards of four feet. I have known," adds Sir J. Richardson, "a dead skunk thrown over the stockades of a trading post produce instant nausea in several women in a house with closed doors upwards of a hundred yards distant. The odour has some resemblance to that of garlic, although much more disagreeable. One may, however, soon become familiarized with it; for, notwithstanding the disgust it produces at first, I have managed to skin a couple of recent specimens by recurring to the task at intervals. When care is taken not to soil the carcass with any of the strong smelling fluid, the meat is considered by the natives to be excellent food. It breeds once a-year, and has from six to ten young at a time."[1] Not fewer than fifteen varieties of this animal have been described, and many of them under separate names, as distinct species. It is singular that the Hudson's Bay variety should approach most nearly to the description of the *Chinche* of Buffon (*Viverra mephitis*, Gmelin), which, though said to be an inhabitant of Chili, is yet regarded by some observers as identical with the skunk of more northern regions, and to the same or closely related species we may also no doubt refer the so-called glutton of Quito (*Gulo Quitensis*), described by Humboldt.[2]

GENUS MYDAUS, Horsfield. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{4-4}{5-5}$; = 34. Muzzle truncated, or pig like. Tail very short.

The only known species of this genus is the *Teledu* of Java (*M. meliceps*, Horsfield), classed as a *Mephitis* by Desmarest and others. In its dentition it certainly agrees closely with the mephitic weasels of America, but its external character and physiognomy are peculiar, its form being heavy, its neck strong and short, and its mode of progression almost entirely plantigrade. It emits an odour very similar to that of the skunk. "The *Mydaus meliceps*," says Dr Horsfield, in his excellent account of this curious animal, "presents a singular fact in its geographical distribution. It is confined exclusively to those mountains which have an elevation of more than 7000 feet above the level of the ocean; on these it occurs with as much regularity as many plants. The long extended surface of Java, abounding with conical points which exceed this elevation, affords many places favourable for its resort. On ascending these mountains, the traveller scarcely fails to meet with our animal, which, from its peculiarities, is universally known to the inhabitants of these elevated tracts; while to those of the plains it is as strange as an animal from a foreign country. A traveller would inquire in vain for the Teledu at Batavia, Semarang, or Surabaya. In my visits to the mountainous districts I uniformly met with it; and, as far as the information of the natives can be relied on, it is found on all the mountains. It is, however, more abundant on those which, after reaching a certain elevation, consist of numerous connected horizontal ridges, than on those which terminate in a defined conical peak. Of the former description are the mountain Prahu and the Tengger Hills, which are both distinctly indicated in Sir Stamford Raffles' map of Java: here I observed it in great abundance. It was the less common on mountain Gede, south of Batavia; on the mountain Ungarang, south of Semarang; and on the mountain Ijen, at the farthest eastern extremity; but I traced its range through the whole island.

"Most of these mountains and ridges furnish tracts of considerable extent, fitted for the cultivation of wheat and other European grains. Certain extra-tropical fruits are likewise raised with success. Peaches and strawberries grow in considerable abundance, and the common culinary vegetables of Europe are cultivated to great extent. To most Europeans and Chinese a residence in these elevated regions is extremely desirable; and even the natives, who in general dislike its cold atmosphere, are attracted by the fertility of the soil, and find it an advantage to establish villages, and to clear grounds for culture. Potatoes, cabbages, and many other culinary vegetables are extensively raised, as the entire supply of the plains in these articles depends on these elevated districts. Extensive plantations of wheat and of other European grains, as well as of tobacco, are here found, where rice, the universal product of the plains, refuses to grow. These grounds and plantations are laid out in the deep vegetable mould, where the teledu holds its range as the most ancient inhabitant of the soil. In its rambles in search of food, this animal frequently enters the plantations and destroys the roots of young plants; in this manner it causes extensive injury, and on the Tengger Hills particularly, where these plantations are more extensive than in other elevated tracts, its visits are much dreaded by the inhabitants; it burrows in the earth with its nose, in the same manner as hogs; and, in traversing the hills, its nocturnal toils are observed in the morning, in small ridges of mould recently turned up.

"The Mydaus forms its dwelling at a slight depth beneath the surface, in the black mould, with considerable ingenuity. Having selected a spot, defended above by the roots of a large tree, it constructs a cell or chamber of a globular form, having a diameter of several feet, the sides of which it makes perfectly smooth and regular; this it provides with a subterraneous conduit or avenue, about six feet in length, the external entrance to which it conceals with twigs and dry leaves. During the day it remains concealed like a badger in its hole; at night it proceeds in search of its food, which consists of insects and their larvæ, and of worms of every kind; it is particularly fond of the common lumbrici, or earthworms, which abound in the fertile mould. These animals, agreeably to the information of the natives, live in pairs, and the female produces two or three young at a birth.

"The motions of the mydaus are slow, and it is easily taken by the natives, who by no means fear it. During my abode on the mountain Prahu, I engaged them to procure me individuals for preparation; and as they received a desirable reward, they brought them to me daily in greater numbers than I could employ. Whenever the natives surprise them suddenly, they prepare them for food; the flesh is then scarcely impregnated with the offensive odour, and is described as very delicious. The animals are generally in excellent condition, as their food abounds in fertile mould."[1]

[2] *Recueil d'Observations sur la Zoologie.*

We may add, that the teledu is by no means ferocious in its manners, and, if taken young, might no doubt be easily domesticated. An individual, retained for some time in confinement by Dr Horsfield, afforded him an opportunity of studying its disposition. It soon became gentle and reconciled to its situation, and never emitted its offensive effluvium. In the natural state, however, its odour is so strong and volatile, that the entire neighbourhood of a village may be infected by a single animal in a state of irritation, and in the immediate vicinity of the discharge the smell is so violent as to produce fainting fits. The specimen from which Dr Horsfield made his drawing ate voraciously of earthworms, but as soon as it had devoured ten or twelve it became drowsy, and, making a small groove in the earth, it placed its snout in it and fell asleep.

Genus Lutra, Ray. Mustela, Linn. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{5-5}{5-5}$ or $\frac{5-5}{6-6}$; $= 36$ or 38. Head flat. Body long and low. Tail strong and depressed at the base.

We here place those amphibious fish-eating animals commonly called otters, of which there are many species. The character and aspect of our European kind (*Lutra vulgaris*, Erxleben, *Mustela lutra*, Linn.) are well known. It occurs over all Europe and a considerable portion of the north of Asia. It is a fierce creature, tenacious of life, and very injurious to fresh-water fisheries, from its habit of preying very exclusively on the upper parts only of trout and salmon, leaving a large portion of the caudal extremity unconsumed. What can be the nature of its objection to this despised portion? In Scotland we find the otter frequently inhabiting the sea-shore as well as the interior, and seeking its food both in salt and fresh water. The female brings forth her young, usually four or five in number, during spring. The fur is valuable, and forms an article of export from our northern isles.

The Canada otter (*L. Canadensis*, Sabine),[2] resembles the European species, both in food and habits, but it is a much larger animal, with a shorter tail, and is distinguished by the fur of the abdomen being of the same shining brown colour as that of the back. It is found across the whole of the northern parts of North America, where, during the winter season, it haunts the falls and rapids for the sake of open water, and when these are frozen over in one district, it will travel a long way in search of others, which may have resisted the power of frost. If pursued by the hunters during these peregrinations, it will throw itself forward on its belly, and slide through the snow for several yards, leaving behind it a deep furrow, and repeating this peculiar movement with such rapidity, that the swiftest runner on snowshoes with difficulty overtakes it. It also doubles on its track very cunningly, dives occasionally beneath the snow, and at last, when too closely pressed to render flight available, it will turn and defend itself with courageous obstinacy. During the spring season, on the Great Bear Lake, this species frequently robbed the nets of Sir John Franklin's first expedition, usually carrying off the heads of the fish, and leaving the bodies sticking in the meshes. It brings forth, in April, from one to three at a birth. Seven or eight thousand skins are annually imported into England.[3]

Another well known American species is the sea otter (*Lutra marina*, Steller), which Dr Fleming, on the supposition that it possesses only four incisives in the lower jaw, desires to constitute a separate genus called *Enhydra*. It is mentioned, however, in the narrative of Cook's (third) voyage, that a young sea otter had six of these teeth as usual in the lower jaw, and it may therefore be inferred that two drop out before the attainment of the adult state. The species inhabits the northern parts of the Pacific from Kamtschatka to the Yellow Sea on the Asiatic shores, and from Alaska to California on those of America. It seems to have more of the manners of a seal than of the land otter, and is sometimes met with out at sea, at a vast distance from the shore; Pennant says even as far as a hundred leagues. The fur is very handsome, and was much esteemed by the Chinese, who gave extraordinary prices for it in former days. The Canton market, however, has long been overstocked, and the influx has of course reduced the value. It varies in beauty with the age and condition of the animal, and the season of the year. Those obtained in winter are of a finer black, and otherwise more perfect than at any other period, and, according to Meares, the male is much more beautiful than the female. Those in highest estimation have the belly and throat interspersed with brilliant silver hairs, while the other parts consist of a thick black coat, with a silky gloss of extreme fineness.

Besides these northern otters we have a Brazilian species, and one (supposed to be distinct) from Carolina, while several Asiatic kinds have been described by Sir Stamford Raffles, Dr Horsfield, and MM. Diard and Leschenhault. The Cape otter (*Lutra inunguis*, F. Cuv.), is alleged to be destitute of claws, and on the supposition of the truth of that negative character, has been formed into a separate genus called *Aonyx* by M. Lesson.[4] He bestows on the sole species the name of *Delalandii*, as it was first brought from the country of the Hottentots, by the French naturalist of that name. It measures about three feet in length exclusive of the tail, which is ten inches. The fur is soft and thick, of a chesnut-brown colour, paler on the flanks, with a mixture of grey about the head. It inhabits the salt pools along the marine shores of the Cape, and preys on fish and crustacea.

2d Subdivision.

Two tuberculous teeth behind the carnivorous cheek tooth of the upper jaw. Body proportionally shorter than in the preceding subdivision, and the limbs longer.

Our present group is mainly constituted by the genera *Canis* and *Viverra* of Linnæus, including the dogs, wolves, and foxes, the civets and ichneumons, besides a few minor genera of recent introduction.

Genus Canis, Linn. Cuv. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars, $\frac{6-6}{7-7}$; $= 42$. The incisive teeth are all placed on the same line, and are usually trilobate, before being worn by use. The upper molars consist of three small single-lobed false molars, one bicuspidate carnivorous cheek-tooth, and two small tuberculous teeth with flattened crowns. The inferior molars consist of four false molars, one carnivorous cheek-tooth, and two tuberculous grinders. The tongue is smooth. The anterior extremities are furnished with five toes, the posterior with four.

[4] *Manuel de Mammalogie*, p. 157.

This genus, of such high importance as containing the numerous and various breeds of our domestic dog, is in one or other of its forms most widely spread over almost all the regions of the habitable globe. We shall not here attempt to give the peculiar characters of the *Canis familiaris*, by which general specific term, if we may be allowed the expression, naturalists are in use to distinguish the domesticated races from the wolves, jackals, and foxes, because their characters are so extremely variable in their nature, and admit of such an extended range of modification, that the exceptions to any presupposed peculiarity are almost as numerous as its confirmations. The more curved form of the tail probably distinguishes all domestic dogs from wolves, while the rounded outline of the pupil serves to separate them from the foxes, in which that organ, when exposed to light, assumes a lenticular shape. We shall proceed to a few general observations on the natural history of these animals, without attempting even an enumeration of the principal domestic kinds.[1]

The real origin of our domestic breeds whether from a single or complex source, may be said to be now entirely unknown, as a subject either of history or tradition. It is lost in the usual obscurity of a remote antiquity, and can now only be ascertained (if at all) by the investigations of the naturalist. So infinitely varied is the external aspect of these invaluable creatures, and so much does it seem to depend, not only on the physical conditions of clime and country under which they exist, but on the moral and political state of the particular nations by whom they are held in subjection, that in numerous instances all traces of resemblance to the supposed original, or indeed to any known species of wild animal, have disappeared; and after the lapse of ages, we are in fact at last presented with what may be termed artificial creatures, incapable of subsisting without the aid and companionship of man, and of which assuredly no natural type ever existed in any age or country. It is clear from what we know of the harmonious laws by which a Divine Providence regulates the economy of the animal kingdom, that no such creature as a pug dog could ever have existed as an independent being in a state of nature, or formed one of those "golden links" by which creation is so softly blended. It would have marred the immaculate beauty of the primeval world.

Many varieties, however, of the domestic dog, though originally produced by what may be termed accidents, have now become permanent subspecies, if we may use the term, each of which is signalised by some characteristic peculiarity of either a physical or instinctive nature, and differs from an ordinary variety (as exhibited among unreclaimed animals), in the power which it possesses of reproducing individuals exactly similar to itself. Several of these varieties from their great value to mankind, have been so encouraged and preserved in purity, as to have become impressed with characters not only distinctive, but of so uniform and permanent a nature as to exhibit in certain instances the aspect of a total difference in kind. Making due allowance, however, for the influence of all extraneous or accidental causes, we yet deem it impossible to doubt that the origin of the dog tribe, as it now exists under the extended dominion of mankind, has been rather complex than simple. We do not mean to maintain that every strongly marked variety has had each its own original source, or that even when nature

> "Wanton'd as in her prime, and play'd at will
> Her virgin fancies,"

there ever existed wild greyhounds, unreclaimed pug dogs, or native pointers and poodles, all alike independent of each other, and of their now acknowledged lord and master, because the question in that case would, from their multiplicity, be speedily set at rest by the occurrence of one or other of these animals in its original and unsubdued condition. But we think it improper to refer the various breeds to one and the same origin, the theory seeming to ourselves more natural which supposes that the characteristic kinds, or great leading varieties of each country or continent, have either directly descended from, or been crossed and remodelled by a union with, such of the native (canine) animals of the same natural genus, as we still find to occur in such country or continent. For example, although we may admit with Guldenstaedt, that the Kalmuc, and some other eastern dogs, may have derived their origin from the jackal, the same cannot be said of those of New Holland, or of North and South America, where the jackal is unknown; and several of our own northern varieties are evidently descended so much more immediately from the wolf, as to render the ancestral aid of the "lion's provider" altogether superfluous. We also know that in America and New Holland, at the period of (and consequently prior to) the discovery of these countries by Europeans, there existed both wild and domesticated dogs, the former of which were evidently indigenous, and in all probability the origin of the latter.[2]

We believe that Pallas was among the first to give currency to the opinion that the dog was to be regarded in a great measure as an adventitious animal, that is to say, as a creature produced by the fortuitous and diversified alliances of several natural species. Both the shepherd's dog and the wolf dog, in his opinion, derive their origin from the jackal, while the mastiff is regarded as more nearly related to the hyena, and the smaller tribes of terriers, &c. to the fox, His ideas, though somewhat fanciful, merit the attention of the naturalist. We object, however, to the hyena, which (though classed with the dogs by Linnæus) is not in fact a canine animal, but belongs to a distinct and well-defined genus, characterized by having five toes on each foot, and five molar teeth on either side of both jaws; whereas the truly canine race, such as dogs, wolves, and jackals, have only four toes on the hinder extremities, with six molar teeth on each side of the upper jaw, and seven on each side of the under. The general proportions of the hyena, too, are very different, the fore-legs being longer than the hind ones, which has the effect of raising the shoulders and anterior portion of the body; whereas in the other species just named, the hind legs are longer than the fore ones, a character which probably obtains among all swift-footed animals. The immediate relationship of the fox is likewise doubtful. His alliance would be useful as giving the *earthy* propensities of the terrier tribes, but we cannot overlook the peculiar shape of the pupil, which is what naturalists call nocturnal, that is oblong, and narrowing under the influence of light; whereas in dogs and other canine species, though it decreases in size under that influence, it retains its circular form. The difference in the habitual character and instinctive habits of the fox must also be borne in mind. It is scarcely necessary to say that it is a wary, silent, nocturnal animal, of sly and solitary habits, never congregating, or hunting its prey in packs, but preferring a gradual and unperceived approach, and the exercise of an insidious cunning, to the more open warfare declared by its congeners. This distinction is in truth of greater importance than may at first appear, for we consider the social or gregarious sentiment in animals as the true basis of a thorough domestication. A solitary species, may, indeed, be tamed, so far as the individual is concerned, but if the social instinct is wanting, its descendants will be only half reclaimed, and the process must be again resorted to. But the love of society, which we call the social instinct, and which is so strongly possessed by sheep, oxen. and other domestic kinds, when once properly directed towards himself by the skill of man, renders these animals forever both attached and subservient to the human race. Another strong objection, though of a more negative kind, to the theories of Pallas and Guldenstaedt, is founded on their slight consideration, if not entire exclusion, of the wolf as the most probable parent, especially in northern countries, of a numerous and important tribe of our domestic dogs. In reference to the point at issue, we indeed regard this animal, as of all others, the most entitled to our strong attention. Many well known varieties of the dog exhibit so wolfish an aspect, that their descent from that species, at a more or less remote period, can scarcely be doubted; and we incline the more to this opinion, when we consider that the jackal is not a northern animal, that the wolf is eminently so; and that the remotest tribes of the human race, inhabiting the highest northern latitudes, have never been found unaccompanied by a domesticated breed of dogs, bearing a greater resemblance to the wolf than to the jackal.

---

[1] We have given a more extended view of the origin and natural history of domestic dogs in the 5th and 6th numbers of the *Quarterly Journal of Agriculture*, and in the first volume of our *Illustrations of Zoology*. genus *Canis*. The reader will find a valuable paper (by another hand) on sporting dogs, under the term HOUND, of this Encyclopædia. See volume xi. p. 762.

[2] For Humboldt's opinion of the indigenous dogs of South America, see *Personal Narrative*, vol. ii. part 2.

All the principal and regulating facts in the natural history of the wolf and dog are identical. The rutting season commences at the same time, and continues for an equal period in each; and both carry their young for nine weeks,—Gilibert's opinion that the period of the wolf's gestation extended to three months and a half having since been proved to be erroneous. Then the jackal is a puny and powerless creature, compared with many of its alleged descendants, while the wolf is one of the strongest of European carnivorous animals. Though those of Spain and Italy are not gigantic, the wolves of Lithuania are extremely large, frequently measuring five feet in length from the muzzle to the insertion of the tail; and the same, or even increased dimensions are maintained by those of still more northern climes. Both their coat and colour vary in accordance with the climate. In high northern latitudes they become white in winter, and a black variety occurs in Spain. This natural variation of the colour of the wolf is a circumstance of some importance in relation to the present inquiry, because the tendency to become white at one extremity of the series, or range of colours, and black at the other, combined with what may be called the central or representative hue of the animal, which is brown, supplies in fact the three elementary colours of the whole tribe of dogs, and thus in a great measure accounts for the variety of markings by which our domestic races are distinguished. In a state of domestication the wolf is capable of assuming and retaining all the docility and gentleness of the dog, and the productive union of the two, though at one time doubted by Buffon, was at an after period ascertained and demonstrated by that brilliant historian of the brute creation, and has since been frequently confirmed in recent times. We shall here rest satisfied with a single citation: "Those naturalists," says Captain Sabine, "who believe that no animal, in a perfectly natural and wild state, will connect itself with one of a different species, will consider the long agitated question of the specific identity of the wolf and dog, as determined by a circumstance of frequent occurrence at Melville Island. In December and January, which are the months in which wolves are in season, a female paid almost daily visits to the neighbourhood of the ships, and remained till she was joined by a setter-dog belonging to one of the officers. They were usually together from two to three hours; and as they did not go far away, unless an endeavour was made to approach them, repeated and decided evidence was obtained of the purpose for which they were thus associated."[1]

Now the only reasonable objection which, as it appears to us, remained to the experiments of Buffon and the younger Cuvier, was deducible from the fact of these having been made upon animals in confinement, and which were consequently existing under constrained and artificial circumstances. But here such objection ceases. We witness the *voluntary* cohabiting of two creatures brought up under entirely different circumstances,—the one with as much of wildness as the most forlorn region of the earth could induce upon an originally savage nature, the other so altered in its form and aspect by the immemorial subjection of itself and ancestors to the dominion of man, as to have lost almost all outward resemblance to the stock from whence it sprung; and yet, notwithstanding this disparity of manners, and the different conditions of the social state, they mutually recognise and acknowledge each other, and the immediate representative of the natural and unaltered species, "like the wild envoy of a barbarous clan," seeks and obtains the affection of the enslaved descendant. Unless all our established notions regarding the legitimate distinctions of species are essentially false, what more do we require to prove the identity of the animals in question?

It is also of importance to bear in mind the existence of wild dogs of the domestic breed, which live in a fierce and emancipated state in the plains and forests of many different countries, because this fact demonstrates that no changes, either physical or artificial, on the earth's surface, whether produced by the agency of man or otherwise, can have extinguished the original source, when its descendants, after regaining their liberty, are thus found to breed and prosper in a state of nature. We insist the more upon this observation, because we think it cuts deeply at the base of a theory, or rather hypothesis, maintained by certain naturalists, who, unable in any way to disencumber the subject, give it the slip by asserting that we must now for ever seek in vain for the original type of our domestic races, in consequence of its extinction, either by universal servitude, or actual extermination. Now, it would certainly be surprising if the original source of the plurality of our domestic dogs had ceased to exist in an independent state, when we see the wild species of so many of our other domestic animals still flourishing in their original positions, notwithstanding their more confined limits, the smaller number of their young, and their comparatively defenceless nature. Those troops of wild (emancipated) dogs which we know to exist in the midst of European colonies, in spite of continued efforts to destroy them, prove that in the infancy and early progress of human society, a naturally wild species could neither be entirely subdued, nor utterly exterminated. Nor is there any evidence whatever from history, tradition, or the geological phenomena of nature, of the extinction of any wild animal of the dog kind; and, as ancient writers mention all the actual species of that tribe in the countries where they still exist, it may more reasonably be concluded that one or more of these wild species are the actual source of our various domestic breeds, than that the source itself has been extirpated.

It is proper, while endeavouring to trace the origin of what Baron Cuvier has called "the completest, the most singular, and the most useful conquest ever made by man,"[2] more especially when we know how ancient that conquest must have been, to refer to the native species of the country usually regarded as the cradle of the human race. From the earliest periods of which we have any detailed records down to the more minutely authenticated histories of modern times, there has never been any indication given of the existence, in Asia Minor, of more than four wild animals of the dog tribe, viz. the hyena, the wolf, the fox, and the jackal. The first of these species, we have already stated, is not now regarded by naturalists as pertaining to the canine race, and we have also referred to certain strongly marked distinctive peculiarities of the fox; so that we consider the wolf and jackal as alone entitled to our particular regard in relation to the present inquiry. We have already said enough to shew the strong claims of the wolf, so far as the northern races are concerned; but the multiplicity of size, form, and locality of our domestic dogs, seems to indicate a compound origin, and it cannot be denied that many of the southern dogs present so marked and peculiar a character, that their descent from the jackal is obvious. It is not our province to enter in this place into anatomical details, but we may state generally, that an attentive comparison scarcely exhibits any sensible difference between the internal structure of the jackal and that of the shepherd's dog. This is the opinion espoused by Pallas and Guldenstaedt, the former of whom maintains that the dogs of the Kalmuks are in truth neither more nor less than jackals. This animal has always abounded in Asia Minor, where all the theogonies of the west have placed the paradisaical cradle of the human race, and where it must have been easily accessible to the first families of mankind. We willingly coincide in this view, with the reservations before mentioned regarding the great northern dogs, and those of the still remoter countries of the New World, where the jackal is unknown, but where its place is amply filled by gaunt and grizzly wolves. It is, indeed, by no means likely that the dogs mentioned by Pietro Martyro and Oviedo, as living with the inhabitants of the little Antilles and the Caraibs of Terra Firma, were derived from species foreign to America; because the authors first named (both of whom were contemporaneous with and witnesses to the discovery and conquest of America) describe these dogs as being of various colours and kinds of coat, from which we may infer that they had been, even then, for a long period reduced to servitude. They were all mute; that is to say, they never barked: but that faculty seems, in truth, to be neither natural nor innate, but rather acquired by habit, as domestic dogs run wild have no other cry than a sharp or prolonged howl; and the silent species of barbarous nations, when introduced into civilized society, speedily acquire the bark of our domestic kinds.

---

[1] *Supplement to the Appendix to* Parry's *First Voyage*, p. 185.

[2] *Règne Animal*, t. i. p. 149.

It may, moreover, be borne in mind, that there are at least two kinds of jackal,—the better known species, commonly called the Indian Jackal (*Canis aureus*, Linn.), and that from Senegal, described by Frederick Cuvier under the name of *Canis anthus.* These animals, though regarded as specifically distinct, have bred together in the Garden of Plants. This is a fact of considerable importance, as shewing the facility with which a mixed breed from the jackal might be procured; and as it was previously known that the wolf manifested the same instinctive inclination towards different varieties of the dog, we thus obtain a more extended knowledge of a feature in the character of the canine race, which throws considerable light upon our inquiries. When we see that both the wolf and jackal thus breed with other species, and that all our domesticated dogs breed with each other, although some are scarcely distinguishable from the wolf, while others seem identical with the jackal, we can scarcely doubt that all such domesticated varieties have in fact arisen primarily from these two animals,—the southern from the jackal, the northern from the wolf; and that the intermediate varieties have sprung from an intermixture of the jackal-dogs on the one hand, and of the wolf-dogs on the other, afterwards crossed and commingled in various conceivable ways, both by accident and design. We confess that the extreme variations are still surprising, if not unaccountable; such as the difference between a lofty limbed and almost gigantic stag-hound of the ancient Irish breed, and the low-legged waddling turnspit, or terrier of the Isle of Skye; but that domestication for many thousand years, and the altered habits of life which ensue from it, have been strongly influential in moulding the form and character of the canine race, is evident from this, that the dogs of all wild and secluded nations, whose domestic animals may be supposed to exist most nearly in a state of nature, are all more strongly allied either to the wolf or the jackall, than those that partake the fortunes of civilized men, who dwell in large cities, or in thickly peopled countries; and this approximation to the aspect of the wild animal in the one case, and departure from it in the other, is in truth the surest index to the primitive types which it is possible to obtain. Thus from two or three original sources or distinct kinds, have been derived about ten times the number of mixed races,—many of which, and chiefly those which lead the most artificial or altered modes of life, have now lost all traces of resemblance to the stock from which they sprung.

The length of the preceding observations will prevent our entering into any detailed account of the infinitely varied dogs of the domestic kind. The subject is, indeed, far too extensive for our present limits, for there is scarcely a nation of the earth, savage or civilized, that does not benefit by their friendly assistance, or derive delight from their affectionate companionship. We doubt not that many tribes of mankind would cease to exist if their dogs were withdrawn from them, and we know of scarcely any which would not suffer severely from such deprivation. Their strength, activity, and courage,—their intelligence, perseverance, and attachment—their exquisite sense of smell—their finely accommodating instincts, and, in many cases, their extreme beauty and grace,—have deservedly rendered the canine tribe the objects of the most unfeigned wonder and admiration to all observers and narrators, whether of ancient or modern days, from Hippocrates to the Ettrick Shepherd.[1]

Having figured, as an illustration of the present genus, the Hare Indian, or Mackenzie River dog (*Canis familiaris*, var. *lagopus* of Richardson, see Plate V., figure 4), we shall here conclude with a few lines in explanation of its history and habits. This variety, as far as yet known, is cultivated only by the Hare Indians and other tribes that frequent the borders of the Great Bear Lake, and the banks of the Mackenzie River. It is too small to be used as a beast of burden, and is therefore employed solely in the chase. It has a mild and demure countenance, a small head, slender muzzle, erect thickish ears, somewhat oblique eyes, rather slender legs, broad hairy feet, and a bushy tail. Though it is covered with long hair, intermingled at the roots with a deal of wool, it differs from the American foxes, and agrees with the wolves, in always having callous protuberances, even during winter, on the soles of the feet and at the roots of the toes. Its size is inferior to that of the prairie wolf, but rather greater than that of the red fox of America. Its resemblance, however, to the former is so great, that, on comparing live specimens, Dr Richardson could detect no decided difference in form (except the smallness of the cranium), nor in the fineness of the fur, nor even in the arrangement of the spots of colour. It bears, in fact, the same relation to the prairie wolf that the Esquimaux dog does to the great grey wolf of the northern parts of the New World, a fact which affords an interesting confirmation of the general views contained in the preceding paragraphs. The Hare Indian dog is very playful and affectionate, and easily attached by kindness. It is, however, not very docile beyond the range of its immediate instincts, and has a great dislike to confinement. Its voice, when injured or afraid, is that of a wolf, but when merely excited or surprised, it makes an attempt to bark, usually ending, however, in a kind of howl. For its size, it is extremely swift and strong. A young one purchased by Dr Richardson from the Hare Indians, became greatly attached to its master, and when not more than seven months old, ran by the side of his sledge upon the snow, for 900 miles, without fatigue. During this long journey, it often carried, of its own accord, a glove in its mouth for a mile or two; but though gentle in its manners, it exhibited but a limited love of learning, and made no progress in fetching and carrying comparable to that of the Newfoundland dog, or many other kinds. It was at last unfortunately killed and eaten by an Indian on the banks of the Saskatchewan, who pretended that he *mistook it for a fox*,—a reason which, according to our European notions, would not so much have led to as deterred from such a meal.[1]

---

[1] The reader who desires a knowledge, or at least a notion of domestic dogs of various kinds, will consult with advantage (in addition, of course, to the various sporting Annals of our own country), Mr Griffith's valuable English edition (with additions) of the *Règne Animal*—the *Menageries* (vol. i.) of the *Library of Entertaining Knowledge*—our essay "On the Origin and Natural History of Dogs" in the *Quarterly Journal of Agriculture* (5th and 6th Nos.)—and Captain Brown's Compendium entitled *Anecdotes of Dogs.*

We shall now say a few words regarding wolves. The common wolf (*Canis lupus*, Linn.) is the fiercest and most carnivorous of the wild animals yet indigenous to Europe. It resembles a large lank-faced, ill-conditioned dog, with a straight tail, a coat of a greyish-fawn colour, and in the adult state, a blackish streak upon the anterior legs. It varies, however, considerably, both in size and colour, according to the nature of the different localities in which it occurs, being larger and fiercer in more northern and unpeopled countries,—feebler and of smaller size when surrounded by enemies, and living in a state of continual fear and precaution. He wanders about in summer during the morning and evening twilight in search of food, which in a sufficing quantity he seldom finds. Frogs, field-mice, and the putrid remains of larger animals, are not despised. The rutting season of the female is in January. She is then followed by numerous males, the strongest or boldest of which having driven away the others, becomes her companion, and seldom quits her till the young have completed their education. When about to bring forth, she prepares her den in some sheltered and secluded spot, which she furnishes with leaves, dried grass, and a portion of wool or hair from her own body. The number of her litter varies from five or six to nine, and the young are born with their eyes closed. For several days the mother never quits them, she herself being carefully fed by the male. She suckles for two months, but about the end of the fifth or sixth week she disgorges half-digested food, and soon after accustoms them to kill and feed upon small animals which she has previously captured. It has been observed that, during this period, the young are never left alone, but are always guarded by one or other of the parents. In about two months they lead them from the covert, and initiate them in the mysteries of the chase. In November or December they begin to wander forth by themselves, but they usually remain more or less united in one family, till the parents are obliged to prepare for another brood.

The wolf in a wild state is a cowardly though cruel animal. He has sometimes been observed so stupified by sudden fear as to be killed or secured alive without danger or difficulty. At the same time, when pressed by hunger, and assembled in troops during the winter season, they become formidable both to man and beast. We know from the ancient chroniclers, and from various legal enactments and feudal tenures, how greatly Britain, especially Yorkshire, was infested by wolves during the days of our Saxon ancestors; and that in the reign of Athelstane it was found necessary to erect a kind of retreat at a place called Flixton, for the protection of passing travellers. Wolves, however, appear to have become almost extinct in England as far back as the termination of the thirteenth century, at least we do not find them recorded as a nuisance after the year 1281. "It is none of the least blessings," observes Hollinshed, "wherewith God hath indued this island, that it is void of noisome beasts, as lions, bears, tigers, pards, wolfes, and such like, by means whereof our countrymen may trafelle in safetie, and our herds and flocks remain for the most part abroad in the field without anie herdsman or keeper. This is chiefly spoken of the south and south-west parts of the island. For whereas we that dwell on this side of the Tweed, may safelie boast of our securitie in this behalfe: yet cannot the Scots do the like in everie point within their kingdome, sith they have grievous wolfes and cruell foxes, besides some other of like disposition continuallie conversant among them, to the general hindrance of their husbandmen, and no small damage unto the inhabiters of those quarters."[2] According to the same authority, the extirpation of wolves from England was imposed as a tribute by king Edgar upon the conquered Welsh. Ludwal, prince of Wales, paid yearly a tribute of 300 wolves, so that in four years none were left. The last seen in Scotland was killed by Sir Ewen Cameron in the year 1680. In Ireland the species was not totally extirpated till about thirty years after that period.

In a state of domestication the wolf can be regarded as nothing more than a dog of a somewhat anomalous and unusual aspect. M. F. Cuvier has more than once rendered them so tame and docile, that but for their unextinguishable love of live poultry, they might have been allowed to wander where they chose. They associated freely and fondly with common dogs, and speedily acquired from them the habit of barking. In general, however, and when left free to manifest their natural instinct, dogs exhibit a great aversion to wolves; and the latter, according to Hearne, frequently slay and devour the train dogs of the Esquimaux. Captain Lyon, who describes the wolves of Melville Peninsula as comparatively fearless, states, that one afternoon a fine dog having strayed a short way ahead of its master, five wolves made a sudden and unexpected rush upon it, and devoured it in so incredibly short a time, that before the gentleman who witnessed the attack could reach the scene of action, the dog had totally disappeared with the exception of the lower part of one leg. In those forlorn regions they frequently came alongside the frost-bound ship, and one night broke into a snow-hut, and carried away a brace of Esquimaux dogs, which appeared to have made a vigorous though unavailing resistance, the ceiling being all besprinkled with blood and hair. So strong, as well as ferocious are these blood-thirsty creatures, in spite of what one might suppose the subduing influence of intense cold, that when the alarm was given, and an armed party proceeded to attempt a rescue, one of the wolves above alluded to was observed, when fired at, to take up a dead dog in his mouth, and to set off with it at an easy canter, although the weight of the victim was supposed to be equal to his own.[3] These and similar facts, apparently of a nature contradictory to the theory of an identity of species which we have previously proponed, is, in truth, in proper accordance with what we know takes place among many other animals, when wild and tame individuals chance to encounter. A strongly marked jealousy, if not positive enmity, seems to exist between the unsubdued members of the same species and such as have passed beneath the yoke. It may be supposed to result, not unnaturally, from that perception of "similitude in dissimilitude" which, according to circumstances, leads alike to the extremes of love or hatred. We have already alluded to the strong instinctive affection which in due season has been seen to exist between them, and we certainly do not conceive that, from a few chance murders rendered almost imperative by the pressure of the times, an argument of any value can be deduced against the natural identity of the wolf and dog.

[2] *Chronicles*, vol. i. p. 378

[3] *Private Journal*, pp. 151, 339, &c.

The black wolf of Europe (Canis *Lycaon*, Linn. *le loup noir*, Buff.) differs very slightly from the common brown species except in colour. Its ferocity, however, is said to be greater. It occurs accidentally in France,—more frequently in Spain and the Pyrenean range. There were two of these black wolves some years ago in the menagerie of the King's Garden in Paris, which every season brought forth young as fierce and mistrustful as themselves, but not like their parents in their colour and external markings. From this circumstance we would hesitate to regard the black wolf as more than an accidental variety. Indeed it has been regarded by some as a mixed race, originally sprung from the common wolf and a black dog run wild among the woods or mountains. The American Indians do not regard the black wolves as distinct from the others, although they abound on the banks of the Missouri, and they report that one or more of that colour are occasionally found in the litter of the common kind.

In regard to the wolves of the New World in general, naturalists do not quite accord in their enumeration of the species. A brown wolf, described as possessing all the characters of the European kind, is said to exist within the limits of the United States; but the more northern American species, though they may possibly approximate those of Siberia and of Lapland, certainly differ greatly in their general physiognomy from the natives of France and the Pyrenees. They are of a more robust and larger form, their hair is longer, finer, and more woolly, their muzzle thicker and blunter, their head larger and rounder, with a sensible depression at the union of the nose and forehead. Except in their superior size and strength, the North American wolves so greatly resembled the sledge dogs of the natives, that our arctic travellers more than once mistook a band of these predaceous animals for the domestic troop of an Indian party. The howl of each is precisely the same.[1] When the deep and long enduring snows of winter have entombed the face of nature in their silent shroud, these creatures often suffer dreadfully from famine, and were they not for the most part as fearful as rapacious, they would assuredly prove most unpleasant neighbours. But the simple expedient of tying an inflated bladder to a branch, so as to admit of its waving in the wind, is sufficient to keep a whole herd at a distance. At times, however, they become more venturous; and at Cumberland House, in 1820, a wolf which had been seen prowling around the fort, and was shot at and severely wounded by a musket-ball, returned again in the dark, streaming with blood, and carried off a dog among fifty others,—the latter howling piteously, but unable to summon courage to attack the gaunt intruder. Sir J. Richardson was even told of a poor Indian woman having been strangled by a wolf, while her husband, who saw the onset of the animal, was hastening to her assistance; but their destruction of human life is most extremely rare. In the spring of 1826, a large grey wolf was driven by hunger to prowl among the huts which had been erected in the vicinity of Fort Franklin, but he attacked no one, and being unsuccessful in obtaining food, he was found a few days afterwards, lying dead upon the snow. This specimen is now in the Edinburgh College Museum, and is exhibited in Plate V., figure 3, of the present work.[2]

We have already alluded briefly to those other canine animals called Jackals, of which there are at least two species. The Asiatic kind *(Canis aureus)*, commonly called the Lion's Provider, occurs over a great extent of territory from India to Palestine, and from Egypt and Barbary, along the shores and through the deserts of Africa to the Cape of Good Hope. Its great voracity, gregarious habits, and wild nocturnal cries, are well known to eastern travellers. It hunts in packs, and the king of beasts, when roused from his royal slumbers by the yells of these insatiate creatures in pursuit of prey, probably follows the hue and cry, and ere long coming up with the slaughtered quarry, comes in for more than a monarch's share of deer or antelope, to the no small chagrin of his so-called providers. The Senegal kind (*Canis anthus*) is characteristic of the western shores, and the Cape jackal *(C. mesomelas*, by some regarded rather as a fox), is found more exclusively at the southern portion of the continent.

Our next group of canine animals contains the Foxes. These may be distinguished both from dogs and wolves by their longer and more brushy tails, their pointed muzzle, and the vertical pupils of their cunning eyes. They also exhale a much more fetid smell. They are of smaller size, but much more numerous in amount of species. On the well-known aspect and character of our common kind (*Canis vulpes*, Linn.) we need not here enter, but shall briefly notice a few of the foreign species.

The arctic fox (*Canis lagopus*) inhabits the most northern lands hitherto discovered. It breeds on the sea coasts, chiefly within the arctic circle, forming its burrows in sandy spots, not isolated as with us, but in little villages of twenty or thirty adjoining. It resembles our European fox in form, but is more densely clothed, of smaller size, and changes its colour in winter from bluish-brown to white. Its fur is of small value compared to that of the red fox, but its flesh, when young, is eatable; while, as an article of food, the other species is extremely disagreeable. The sooty dog of Pennant,[3] and the blue fox described by Sir George Mackenzie,[4] are merely varieties of this arctic species.

The red fox of North America (*Canis fulvus*, Desm.) inhabits the woody districts of the fur countries. About 8000 skins are imported into England every year. Pennant, and most authors of the last century, regarded this species as identical with our common European kind; but its peculiarities have since been pointed out by M. Palisot de Beauvois. It is distinguished by its longer and finer fur, and more brilliant colouring. Its cheeks are rounder,—its nose thicker, shorter, and more truncated,—its eyes are nearer to each other, and its feet generally much more woolly beneath. It has a more copious brush, and is altogether a larger animal. Yet it does not possess the enduring speed of the British renard, its strength appearing to be exhausted at the first burst, after which it is easily overtaken either by a mounted huntsman, or its enemy the wolf. The red fox preys much on small animals of the rat kind, is fond of fish, and in fact rejects no animal substance of any kind. The American cross fox (*Canis decussatus*, Geoff.) is probably a variety of the preceding, although it is usually of smaller size. Its fur is much esteemed, a single specimen not many years ago being worth from four to five guineas, while that of the red fox did not bring more than fifteen shillings. A rarer and still more valuable variety is the black or silver fox (*Canis argentatus*, Desm.), of which never more than four or five individuals are taken at any one post of the fur countries throughout the year, although the hunters leave no device untried. It varies from a mixed or hoary hue to a shining black. La Hontan says, that in his time the skin of a black fox was worth its weight in gold, and it still fetches six times the price of any other fur obtained in North America. Various additional species of the fox tribe have been described by naturalists.

[4] *Travels in Iceland*, p. 327.

Genus Megalotis, Illiger. *Fennecus*, Desm. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{6-6}{?-?}$; $=?$ Muzzle pointed. Ears extremely large. Four (?) toes on each foot.

Great contrariety of opinion has existed among systematic naturalists regarding the nature and affinities of the animal described by Bruce, the Abyssinian traveller, under the name of *fennec*,—the *Animal anonyme* of Buffon; and we regret to say, that in addition to merely scientific discussion, some not very amiable inferences have been deduced by that spirit of rivalry, which though useful as an exciting motive, and as a disturber of lethargy, is sometimes apt, in acrimonious minds, to overflow the bounds of Christian charity. The discovery of the animal in question, though usually assigned to Bruce, was likewise claimed by a Swedish gentleman, M. Shioldebrand, who is asserted by the former to have got the start of him in this matter by some petty artifice. Neither the one nor the other, however, it has been observed, has described the species with such a degree of scientific accuracy as to afford us any aid in determining its true position in the system, and the consequence has been, that each subsequent writer has placed it in a different genus. Some have classed it with the cats, others among the canine tribes. Illiger made it the type of a new genus, under the name of *Megalotis* (which we here adopt), while it has been occasionally placed with the squirrels in the order *Glires*, and was even at one period published by the skilful G. St Hilaire as a quadrumanous animal, belonging to the genus *Galago!* Although thus known under a sufficient number of appellations, it is nevertheless most commonly called the "Anonymous animal," as if it had no name at all; and while one writer describes it as inhabiting the desert wastes of the Sahara, where it is alleged to excavate for itself a subterranean dwelling, another assures us that it dwells habitually amid the plumy summits of the loftiest palm-trees. In consequence of these contradictory statements, some later authors seem inclined to deny its existence altogether, while others allege that the so called anonymous animal constitutes in fact a distinct genus, consisting not of one but of two easily distinguished species.

Buffon is known to have published his figure of the fennec from a drawing transmitted to him by Bruce. As the views of the great French writer were extremely fanciful in relation to arrangement, we need not be surprised that he should have placed it between the squirrel and the hare. It certainly has long ears and a somewhat bushy tail; and we have seen enough of what are called *affinities* in modern times, to palliate the vagaries of our imaginative predecessors. Blumenbach, from Bruce's description, refers it to the civets. Sparrman maintains its identity with a species of the south of Africa called *Zerda*,—in consequence of which it continues to bear that name in many systematic works. Desmarest follows Illiger in making it the type of a new genus,—the name of which, however, he changes to *Fennecus*. We need scarcely say, that by these repeated transpositions but a feeble light was thrown upon its actual nature. More recently, however, the Museum of Frankfort was visited almost simultaneously by two intelligent zoologists, M. Temminck and Dr Sigismond Leuckart of Heidelberg, both of whom immediately recognised the fennec of Bruce in an animal then recently transmitted from Dongola by the traveller Rüppel. As the result of their investigations, and of those of others since continued, to which we have had private access, there now remains no doubt that the fennec is closely allied to the canine race, being most related to the subdivision which contains the foxes, and approaching particularly to the *Canis corsac*. The teeth, the feet, the number of toes (?), and the form of the tail, are said to be the same as those of a fox;—but the limbs are higher and more slender in proportion. The aspect of the head is rendered peculiar by the extraordinary size of the ears. Our information is still defective regarding the manners of this species, but it appears to be the opinion of those who have studied its character and history, that the fact reported by Bruce of its living on trees is erroneous, and that it is more probably a ground or even a subterranean animal, supporting itself, in a state of nature, on small quadrupeds and birds.[1] Of the individual observed by Bruce the favourite food was dates, or any other sweetish food; yet it was observed to be very fond of the eggs of small birds. When hungry it would eat bread, especially when spread with honey; but when a small bird passed near, it was observed to engross for a time the fennec's whole attention, and to be followed, while within the range of sight, with eager eye. It became unquiet and restless as soon as night came on, from which we may infer a nocturnal nature. Its body measured about ten inches long, the tail five, the ears three. The pupil of the eye was large and black, and surrounded by a deep blue iris. It had a sly and wily aspect, but as its habits are not gregarious, and for other reasons, Bruce doubts the propriety of this creature being regarded as the *Saphan* of the Scriptures,—an opinion advocated both by Jewish and Arabian writers.

The genus now consists of two species, the fennec of Bruce, above alluded to (*M. Brucii*, *Canis zerda* of Gmelin), which will be found figured in Plate V., figure 6; and Delalande's fennec (*M. Delalandii*, Smith, *Canis megalotis*, Cuv.), which is native to the Cape of Good Hope.[2]

We may notice in this place another singular canine animal from the Cape, which seems to have likewise received a multiplicity of names. It occupies, as it were, a station intermediate to that of the dogs and hyenas, and although long known to the colonists under the designation of wild dog, and alluded to by many travellers, its distinctive peculiarities were first pointed out by Mr Burchell, who describes it under the name of *Hyæna venatica*.[1] In the number of its teeth it agrees with the dogs, but it has only four toes on the anterior feet, and its body is hyæna-like in its form, being considerably higher before than behind, with the joints of the carpus very weak. If classed with the true dogs, its most appropriate title would be *Canis hyænoides*, but it is understood that Mr Brooks (in whose splendid museum there existed a skeleton of the animal) regarded it as a distinct genus, and we find it recorded as such under the name of *Lycaon tricolor*.[2] The general colour of this animal is a sandy bay or ochreous yellow, shaded with darker hairs, and the entire body is blotched and brindled with black and white spots. Mr Burchell kept a specimen for thirteen months chained up in a stable-yard, but its nature was ferocious, and although at last it began to gamble occasionally with a common dog, yet its keeper never dared to touch it with his hand. In its native state it hunts in regular packs, both by day and night, and is so rapid in its movements, that none but the swiftest animals can ensure their safety. Sheep fall an easy sacrifice, but the larger cattle are seldom attacked, except stealthily from behind, for the sake of snapping off their tails,—the want of which, our readers may be assured, in a warm country, swarming with hide-piercing insects, is the source of most serious distress to any quadruped. "In the morning," says our traveller, "Philip returned with the oxen; but reported that, in consequence of Abram Abram's neglecting in the night before to secure them as usual in the cattle-pen, the *wilde honden* (wild dogs) had bitten off the tails of three. One had only lost the brush, but the others were deprived of the whole!" The animal in question is of a more slender form than either the striped or the spotted hyæna.

---

[1] *Edinburgh Cabinet Library*, No. xii. p. 390.

[2] For figures and descriptions of these animals, see Bruce's *Travels*, plate 28; Griffith's *Animal Kingdom*, vol. ii. p. 372; and Ruppel's *Reise im Nördlichen Afrika*, pl. 111. The ears in Bruce's figure are too large.

GENUS VIVERRA, Linn., Cuv. Incisors $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{6-6}{6-6}$; = 40. The lower incisives are placed on the same line, and the canines are rather strong. The upper molars consist, on each side, of three false molars, slightly conical and compressed, of a large carnivorous cheek-tooth, sharp, cutting, and tricuspidate, and of two tuberculous grinders. The lower jaw presents four false molars on each side, a strong carnivorous bicuspidate cheek-tooth, and a single very broad tuberculous grinder. The head is long, the muzzle pointed, the pupil narrow when contracted, and the tongue covered by corneous papillæ. Each foot is furnished with five toes, and the claws are semi-retractyle. The tail is long and covered with hair.

This genus, as now restricted (the ichneumons no longer forming one of its constituent portions), contains the animals commonly called *civets* and *genets*, all remarkable for their musky odour. They are peculiar to the warmer countries of the ancient world, and their habits, in a state of nature, are as yet but slightly known.

The civets properly so called (VIVERRA, Cuv.), are distinguished by a deep anal pouch divided into two interior sacks, and filled with a musky pomade, of considerable commercial value as an article of perfumery. The species occur both in Asia and Africa. Enfras, a town of Abyssinia, is said to carry on an extensive civet trade, great numbers being there kept in a state of confinement. The *V. civetta* and *zibetha* of Linnæus are still insufficiently distinguished. They are very closely allied to each other, but the former is said to be characteristic of Africa, the latter of the East Indies. Dr Horsfield has described a third species called *Rasse* by the Javanese. Its appetite is very sanguinary in a state of nature, and leads it to prey on birds and quadrupeds. In confinement it agrees well with a mixed diet of rice and animal food. It yields the odoriferous substance called *dedes* in Java, the *jibet* of the Malays. This perfume is a great favourite in Java, where, during festal days and public processions, the air is diffusively filled with its odour. Salt is said to be a poison to the animal which yields it.

In the group or subgenus called genets (GENETTA, Cuv.) the anal bag is reduced to little more than a fold of the skin, and the secretion is very slight, though there is a sensible exhalation of a musky odour. The pupil, when exposed to light, is vertical, and the claws are almost as retractile as those of cats. The common genet (*V. genetta*, Linn.) is a European species, widely extended in its distribution from the south of France to the Cape of Good Hope. It varies considerably in its markings, and its fur forms an article of commerce. Other species occur both in Africa and the East. The rare Javanese animal the *Delundung*, which seems in some respects intermediate between the viverræ and the cats (it forms the genus PRIONODON of Dr Horsfield), is ranked by Baron Cuvier with the genets.

We may here briefly notice a peculiar species long known to systematic writers under the name of palm marten and *Genette de France*. Its dentition and the majority of its other characters agree with those of the genets, but its form is thicker, its toes semi-palmate, and its walk almost plantigrade. Its most peculiar character, however, consists in the form of the tail, which is spirally rolled, though not prehensile. It now forms the genus PARADOXURUS of F. Cuvier, of which his brother the Baron admitted of only a single species (the animal just alluded to), under the name of *P. typus*, shown in Plate VI., figure 1. It is called *Pougouné* in India. If, as is generally supposed, it is also synonymous with the *Musanga* of Java, then the following particulars, communicated by Dr Horsfield, will apply to both. The musanga is most abundant near villages in the vicinity of the larger forests. It constructs its nest in the fork of a branch, or the hollow of a tree, of dry leaves, small twigs, and grass, and sallies forth at night in search of eggs and chickens. It also robs gardens of various kinds of fruit, is particularly fond of pine-apples, and devours coffee-berries in such quantities as to be very destructive in plantations of that commodity.[3]

GENUS HERPESTES, Illiger. *Ichneumon*, Lacepede. Incisors $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{5-5}{5-5}$; = 36. Body elongated, and low upon the legs. Head small and pointed. Eyes susceptible of being covered with a nictitating membrane. Ears short and rounded. Feet with five toes, armed with sharpish semi-retractile claws. Tail long and pointed. Anal pouch large, but simple.

This genus, according to Geoffroy,[4] contains nine species, of which four are from India or the Indian Archipelago, one from Madagascar, two from undetermined regions, one from the Cape, and one from the north-east of Africa. The last is the celebrated ichneumon (*Herpestes Pharaonis*, Desm.), so noted in the mythology of ancient Egypt. It is larger than a cat, and shaped like a marten, the fur composed of hairs ringed with brown and fawn colour. The paws and muzzle are black, and the tail terminates in a diverging tuft. The ichneumon, "presenting a lively image of a beneficent power perpetually engaged in the destruction of those noisome and dangerous reptiles which propagate with such terrible rapidity in hot and humid climates," was adored by the Egyptains. It still abounds in the northern parts of the country, that is, between the

---

[1] It is the *Hyæna picta* of Temminck, and the *Canis pictus* of Desm. See also the 2d volume of Burchell's *Travels*, and Griffith's *Animal Kingdom*, vol. ii. p. 376.

[2] *Synopsis of Mammalia*, p. 151. One of its previous *specific* names ought assuredly to have been retained.

[3] Some uncertainty seems to prevail in regard to the affinities which exist between the Bentourong of Raffles (ICTIDES?), and the genus above named.

[4] *Description de l'Egypte*, Hist. Nat. t. ii. p. 140.

Mediterranean and Siout, but it is rare in Upper Egypt. It preys on rats, reptiles, and the eggs both of birds and crocodiles, and is itself attacked by foxes, jackals, and the animal called Tupinambis. It is not bred in confinement by the modern Egyptians (who call it *Nems*), but being easily domesticated when taken young, and of kindly docile habits, it is often brought up as a kind of pet about their houses. Like cats, these animals acquire a strong attachment to particular dwellings, and readily recognise the voice and person of their master.

The Indian species, commonly called the *mangouste* (*H. mungos*, Desm.), is less in size than the preceding, its colour paler and more grey, and its tail pointed. It is celebrated, like its brother of the Nile, for its destruction of poisonous snakes and other reptiles, and is still more deservedly renowned for its strange instinctive discovery of the medicinal virtues of the plant called *Ophiorhiza mungos*, as an antidote to the otherwise fatal effects of their envenomed fangs. Another nearly allied species is the *Ichneumon griseus* of Desmarest (*Viverra cafra*, Gmelin). It is easily domesticated, and thrives well on bread and milk. Yet its carnivorous propensities are unsubduable, and it cannot be trusted in the vicinity of caged birds or poultry. It may be rendered useful in the destruction of rats and other vermin. This animal is said to occur both in India and the south of Africa. To it M. Geoffroy has (we think erroneously) applied the name of mangouste *nems*, thus bestowing an Egyptian name upon a species which assuredly occurs not in the country of the Pharaohs.

GENUS RYZÆNA, Illiger. *Surikata*, Desm. Incisives, $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{6-6}{6-6}$; = 40. Four toes on both the anterior and posterior extremities.

This genus is constituted by the Surikate alone (*Viverra tetradactyla*, Linn.), an animal from the south of Africa, of a nature intermediate between the pole-cats and ichneumons. It is easily tamed, and, like a cat, becomes attached to its own dwelling. Buffon erred in deeming it a native of America.

We shall terminate this subdivision of the Digitigrada by the notice of a singular animal from the southern parts of Africa, which conducts us naturally to the hyenas. We allude to the *Proteles Lalandii* of Isidore G. St Hilaire,[1] formerly regarded as a genet, and named provisionally *Viverra hyænoides* by Baron Cuvier. It was originally transmitted from the Cape by M. Delalande, and belongs undoubtedly to a distinct genus. Its cranium partakes of the characters of the dogs and civets, and, like the canine tribes, it bears a fifth or rudimentary toe upon the fore feet; but its raised shoulders, sloping back, and all its outer aspect, are precisely those of a hyena, even to the radiated markings of the fur. It is a nocturnal animal, an inhabitant of the banks of the Fish River in Caffraria, and is supposed to have been examined as yet only in an immature condition. Its teeth amount to thirty, of which four are canine, twelve incisives, with eight molars in the upper jaw, and six in the under; but there is reason to believe that our knowledge of its true condition is as yet imperfect. (See Plate VI., figures 2 and 2 *a*.)

3D SUBDIVISION.

No tuberculous tooth behind the large carnivorous cheek-tooth of the lower jaw.

This subdivision consists of the most bloodthirsty and carnivorous of the class, and contains the Linnæan genus *Felis*, with the addition of the hyænas, which the great Swedish naturalist placed in the same genus as the dogs and wolves.

GENUS HYÆNA, Storr, Cuv. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{5-5}{4-4}$; = 34. All the extremities with four toes. There are three false molars above, and four below, all conical, blunt, and singularly large; the upper carnivorous cheek-tooth has a small tubercle within anteriorly, but the inferior presents only a couple of strong cutting points.

The great size of the teeth in this genus, combined with the extraordinary strength of the muscles of the jaws and neck, bestow upon it a tremendous power of mastication, by means of which the species can crush to atoms the bones of the largest and most obdurate prey. Their hold is indeed so strong, and so tenacious, that it is almost impossible to wrest any thing from them when once enclosed within their iron fangs. Hence, among the Arabians, their very name is used as the symbol of obstinacy. Hyænas generally inhabit caverns and other rocky places, from whence they issue under cover of the night to prowl for food. They are gregarious, not so much we think from any social principle, as from a gluttonous and grasping instinct, which induces many to assemble together even over the most insufficient meal. They are accused of violating the sepulchres of the dead, for the sake of devouring whatever bodies they can disinter, or may chance to find but hastily inhumed. From such notions, however slightly founded, we usually associate a peculiar gloominess and malignity of disposition with the aspect of these creatures, and the name of "laughing hyena," which one of them bears, seems to render their character still more unnatural and revolting. We fancy them indulging in their horrid mirth, like reckless resurrectionists,—their hilarity increasing as they tear the protecting cerements from the dead man's grave. Like any other animal, however, the hyæna is perfectly capable of being tamed, and indeed a contradictory feature in regard to diet has been observed even in the manifestation of its natural and unbiassed instincts. About Mount Libanus, Syria, the north of Asia, and the vicinity of Algiers, the hyænas, according to Bruce, live mostly upon large and succulent bulbous roots, especially those of Fritillarias, &c.; and he informs us that he has known large patches of the fields turned up by them in their search for onions and other plants. He adds, that these were chosen with such care, that after having been peeled, if any small decayed spot became perceptible, they were left uneaten. In Abyssinia, however, and many other countries, their habits are certainly exclusively, or, at least, decidedly carnivorous, although the same courage or rather fierceness which an animal diet usually produces does not so obviously manifest itself. In Barbary, according to the same authority, the Moors, in the daytime, will seize the hyæna by the ears and drag him along, without his resenting such ignominious treatment otherwise than by attempting to draw himself back; and the hunters, when his cave is large enough to give them entrance, take a torch in their hands, and advancing straight towards him, pretend to produce fascination by the utterance of some senseless jargon. The creature in the mean time becomes so astounded by the unaccustomed noise and lurid glare, that he allows a blanket to be cast over him, and unresistingly succumbs to fate. Bruce one day locked up a goat, a kid, and a lamb, with a Barbary hyæna which had fasted, and in the evening he found the intended victims not only alive but quite uninjured. He repeated the experiment, however, on another occasion, during the night, with a young ass, a goat, and a fox, and next morning he was not unreasonably astonished to find the whole of them not only killed, but actually eaten, with the exception of some of the ass's bones! This was pretty well for an animal so curious in bulbous roots. Yet the experience of the narrator was undoubtedly great. "I do not think," says the Abyssinian traveller, "there is any one that hath hitherto written of this animal who ever saw the thousandth part of them that I have. They were a plague in Abyssinia in every situation, both in the city and the field, and I think surpassed the sheep in number. Gondar was full of them from the time it turned dark till the dawn of day, seeking the different pieces of slaughtered carcasses which this cruel and unclean people expose in the streets without burial, and who firmly believe that these animals are Falasha from the neighbouring mountains, transformed by magic, and come down to eat human flesh in the dark in safety." On entering his tent one night he perceived two large blue eyes glaring at him from the head of his bed. It was a hyæna with several bunches of candles in its mouth, but which immediately paid for its temerity as a tallow-chandler with its life.

---

[1] *Mem. du Mus.*, t. xi. pl. 20.

Africa is the true country of hyænas, although the striped species (*Hyæna vulgaris*, Desm., *Canis hyæna*, Linn.) extends into western Asia. The spotted or Cape hyæna (*H. capensis*, Desm., *Canis crocuta*, Linn.) resembles the species just named except in the external markings of the fur. It carries the posterior part of the body very low, owing to the articulations of the hind legs being constantly bent. It is apt to feel dazzled by strong light, which gives an appearance of indecision to its movements during the day. It is easily tamed, and, according to Sir John Barrow, is trained in the district of Schneuburg for the service of the chace. The third species (which we here figure as an example of the genus, see Plate VI., figure 4) is called the brown hyæna (*H. brunnea*, Thunberg,[1] *H. villosa*, Smith).[2] It is likewise a native of Southern Africa, and is characterized by the blackish rays upon its legs.[3]

Genus Felis, Linn. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{4-4}{3-3}$ or $\frac{3-3}{3-3}$; $= 30$ or 28. Of the four molars of the upper jaw two are conical or false molars, one is a very large three-lobed carnivorous cheek-tooth, and the fourth (wanting in some of the species) is a small tuberculous tooth, broader than long. The molars of the under jaw consist of two simple compressed false molars, and one bicuspidate carnivorous cheek-tooth. There is no tuberculous tooth in this jaw, but its functions are performed by the inner lobe of the cheek-tooth, the rounded point of which, when the jaws are closed, is brought into contact with the flattened surface of the upper tubercular grinder. Head and muzzle short. Anterior feet with five toes, the posterior with four, all strongly armed with sharp, curved, retractile talons, held backwards in repose. Tongue rough, with horny papillæ pointing backwards.

The feline race, containing the most bloodthirsty and ferocious of animals, is characterized by an organic structure admirably adapted to the wants and habits of its numerous species. These differ greatly in size and colour, but resemble each other in shape and general proportions. The genus is distributed over the whole world, with the exception of Australia and the polar circles.

In a state of nature animals of the cat kind are almost continually in action both by night and day. They either walk, creep, or advance rapidly by prodigious bounds, but they seldom *run*, owing, it is believed, to the extreme flexibility of their limbs and vertebral column, which do not preserve the rigidity suitable to that species of progression. Their sense of sight, especially during twilight, is acute, their hearing very perfect, their perception of smell less so than among the canine race. Their most obtuse sense is supposed to be that of taste;—the lingual nerve in the lion, according to Desmoulins, being no larger than that of a middle-sized dog. The tongue of these animals is in truth almost as much an organ of mastication as of taste, the sharp and callous points with which it is covered being used for tearing away the softer parts of the animal substances on which they prey. The perception of touch is said to reside in great perfection in the small bulbs at the base of the whiskers.

We have elsewhere stated our opinion, that all that has been said regarding the noble generosity and superior courage of the lion and other species of the race, is considered by naturalists to be purely fabulous.[4] They seize their prey by surprise, lying in treacherous ambuscade, or gliding insidiously through dark ravines; and are constitutionally of a nature so shy and mistrustful, that if they fail in their first attempt upon the life of even an insignificant creature, they rarely renew it again upon the same individual. Neither does their ferocity by any means imply, as so frequently supposed, the fatal necessity of murder; for the instinct to destroy is only the sensation of hunger in animals having a propensity to flesh, and provided with the means of obtaining it. This instinct is itself effaceable by an artificial supply of food, provided continuously and in abundance. No existing animal (we mean of course of the higher classes,—inhabitants of the same element with ourselves) is rendered incapable, by the constitution of its nature, of being ameliorated by the art of man. The bloodthirsty jaguar of America plays with its keeper, as a kitten does with a child; and our menageries of recent years have exhibited many Bengal tigers of very mild and gentle manners.

The females are remarkable for their tender attachment to their young, while the males are distinguished by a peculiar jealousy, as it may be called, which frequently renders them the most formidable enemies of their own offspring. Hence it is, that the former sex usually conceal the places of their "procreant cradle," or frequently remove their young. They are, upon the whole, a solitary tribe (although young lions sometimes assemble together in small family groups), and, like most animals which feed on living prey, rarely seek each other's society except during the season of love. Like the "mighty hunters" among the human race, they require an extensive domain for the exercise of their predacious habits, and a near neighbour can therefore be regarded only as a mortal foe. It is the uneradicable nature of this sentiment which causes that peculiar noise in the throat and the mistrustful rolling of the eye, observable even in the most perfectly reclaimed individuals, when they are approached during meal-time. The cry varies greatly in the different species. The lion, when in that mood "of stern disdain at which the desert trembles," roars with a voice resembling distant thunder, deep, tremulous, and broken; the jaguar barks almost like a dog; the cry of the wily panther is like the grating of a saw; and most of them, when pleased, appear to *purr* after the manner of our domestic cat, with an energy proportioned to the size of the species.

---

[1] *Mem. de l'Acad. de Stock.* 1820, part i. pl. 2.

[2] *Linn. Trans.* vol. xv. pl. 19.

[3] The *Canis* (*Hyæna*) *Hyænomelas* of Bruce is nothing more than a variety of the common striped species. The *H. venatica* of Burchell (*H. picta*, Tem.) has been already noticed under another head. The fossil species do not fall within the province of the present article.

[4] *Illustrations of Zoology*, vol. i. Genus Felis.

It would be inconsistent with the nature and prescribed extent of the present treatise to enter into descriptive details of the numerous and diversified species of which the genus Felis is composed.[1] The following notices must therefore be few and brief.

The lion (*Felis leo*) king of beasts, is easily distinguished by his uniform tawny hue, his large and flowing mane, and tufted tail. His general aspect is indeed strikingly bold and magnificent. His large and shaggy mane, surrounding his imperial front,—his bright commanding eyes, which upon the least excitement seem to glow with unearthly lustre,—his magnanimous and lofty countenance, symbolical of boldness from remote antiquity,—to say nothing of his muscular limbs, extensile talons, and the irresistible armature of his deadly jaws,—certainly embody our liveliest conceptions of warlike grandeur, and of a power not unbefitting his assumption of regal sway. The southern parts of Africa produce a variety of which the mane is nearly black. Those of Barbary are brown, with a very thick mane covering the neck and shoulders of the male. In Senegal they are of a yellow hue, with thinner manes. The Asiatic lion seldom attains to the dimensions of the South African kind, and his colour is paler and more uniform. Modern naturalists seem inclined to regard some of these animals as of different species, according to their natural localities, but they have as yet failed to point out satisfactory characters for their specific separation; and their general reasoning on the subject is rather hypothetical than conclusive.

The geographical distribution of the lion seems to have become greatly circumscribed within these last two thousand years, for from many districts where it formerly abounded it has now entirely disappeared. According to Herodotus it was once sufficiently common both in Thrace and Macedonia, and it is also known to have abounded in Asia, from the shores of Syria to the banks of the Ganges and the Oxus. The vast numbers brought together by the Romans during the games of the circus have been often recorded.

Inferior to the lion in the majesty of his deportment, but nearly equal in size and strength, and perhaps superior in activity, is the tiger (*Felis tigris*), a familiarly known, but greatly dreaded feline animal, of which the external characters need not to be here detailed. This "most beautiful and cruel beast of prey" has a more slender body, and a smaller and rounder head than his great congener. His motions, notwithstanding his vast deceptive bulk, are full of graceful ease and lightness; and the rich tawny yellow of the prevailing portion of his coat, contrasted with the numerous sloping lines of black, and the pure white of the under portions of his body, render him one of the most perfect pictures of savage beauty presented by the brute creation. The geographical distribution of this gorgeous tyrant of the East is much more extended (so far as Asia is concerned, for he does not occur in Africa) from south to north than that of the lion, as he not only advances far into those desert countries which separate China from Siberia, but is also found between the Irtysch and the Ischim, and even, though rarely, as far as the banks of the Obi. In a longitudinal direction, however, there is a much greater restriction of the one species than of the other, as the tiger appears but rarely to pass to the westward of a line drawn from the mouths of the Indus in a northerly direction to the shores of the Caspian Sea. The species was therefore much less familiarly known to ancient writers than the lion, and Megasthenes alone among the Greeks seems to have been acquainted with it from personal observation. Aristotle mentions it merely as an animal of which he had heard by name; and, even among the Romans, it was long regarded as of extreme rarity. Claudius exhibited four at one time, and it has been reasonably conjectured that the beautiful mosaic picture of four tigers, discovered a good many years ago in Rome, near the Arch of Gallienus, was executed in commemoration of so striking and unprecedented a display.[2]

The panther (*Felis pardus*, Linn.), the *pardalis* of ancient writers, is believed to occur over a great portion of Africa, the warmer parts of Asia, and the islands of the Indian Archipelago. It is usually marked along the sides with six or seven rows of black spots, each spot being itself composed of five or six small simple spots ranged in a circle. The leopard (*Felis leopardus*, Linn.) is a species closely allied to the preceding, but marked with ten rows of smaller spots, and believed to be confined to Africa. The hunting tiger or chittah (*Felis jubata*, Schreber), one of the most lively and elegant of the genus, is less than the panther, of a more slender form, and proportionally higher in the legs. Its toes are lengthened like those of a dog, and its claws, very slightly retractile, are blunter and less curved than in any other species of the cat kind. It is an Asiatic animal well known in eastern countries as an accessary in the chase of antelopes. The extent of its geographical distribution is still, we think, obscure. According to Thunberg it is common in the south of Africa,—a fact confirmed by Lichtenstein, who saw the chief of a horde of Caffres clothed in its beautiful and sumptuous skins; Temminck has ascertained its existence along the western shores of that division of the world; and several specimens have been lately transmitted from Nubia by Ruppel to the Frankfort Museum. Now the range is so great from the north of Africa to the far forests of Sumatra, where hunting tigers likewise abound, that observers have surmised that two species have been probably confounded under one name. Those from eastern countries are said to be more dog-like, to have longer legs, and a scantier mane. The chittah is known in Persia by the name of *youze*, and naturalists are of opinion that many of the skins received by furriers from Senegal and other parts of Africa, are identical with those of the hunting tiger of Hindostan. Many other feline species occur in Asia, Africa, and the eastern islands.

In the New World animals of this genus are likewise very numerous. Of these one of the most noted is the great panther of the furriers, *tigre d'Amerique* of the French, commonly called the jaguar (*Felis onca*, Linn.). It is a fierce and dangerous species, of which the habits have been well described by Humboldt, Azara, and other writers. Its general colour and aspect resemble those of the preceding spotted species, but it is of greater size, proportionably lower on the legs, with a larger head, and the circular spots, ranged along the sides in four rows, have usually each a smaller spot in the centre. The jaguar inhabits the forests which skirt the magnificent rivers of South America, and is by far the most formidable animal of the New World, where it is held in great dread by the native tribes, who are impressed with the belief that it prefers their flesh to that of white men. They are probably what the Highland schoolmaster would call more accessible, being less incumbered with clothing. While travelling, they light great fires during the night, from the notion (we believe well founded), that most wild animals fear the restless glare of that fierce element; yet, of six men stated by Azara as having been devoured by jaguars, two were carried away from the immediate precincts of a blazing fire at which they bivouacked. This animal so greatly abounded in Paraguay before the expulsion of the Jesuits, that 2000 are known to have been slain in a single year. Humboldt mentions, about the same period, that more than 4000 jaguars were killed annually throughout the Spanish colonies, and that 2000 skins were formerly exported every year from Buenos Ayres alone. No wonder that a cheerful fire, amid the damp recesses of the forests, should be there found less pleasant than in colder climes.

---

[1] Most of these may be found in two works very accessible to all classes of readers,—the *Naturalist's Library*, edited by Sir W. Jardine (Mammalia, vol. ii.), and the *Miscellany of Natural History*, edited by Sir T D. Lauder (vol. ii. Feline Species). See also Griffith's *Animal Kingdom*, vol. ii, Desmarest's *Mammalogie*, p. 216, Temminck's *Monographie de Mammalogie*, t. i. p. 73, the Atlas to Ruppell's *Reise im Nordlichen Africa*, Azara's *Voyage au Paraguay*, and his *Essai sur l'Hist. Nat. des Quadrupedes* of that country, and Wilson's *Illustrations of Zoology* as last referred to.

[2] See *Ossemens Fossiles*, t. iv. p. 415. We do not think it necessary to burden our pages with anecdotes of tiger-hunting, &c. as these are to be met with (more than enough) in so many accessible volumes.

Another fierce, but less powerful species of the New World, is the puma or American lion (*Felis concolor*, Linn.). It is almost the only animal against which the charge of wanton or unnecessary cruelty seems well founded. It has been known to kill fifty sheep at one time, for the sake of sipping a little of the blood of each. Its manners differ considerably from those of the jaguar. It rather inhabits plains than forests, and approaches nearer to the habitations of man. In ascending a tree it is said to spring up at a single leap, and to descend in the same manner; while the jaguar runs up exactly like a common cat. Notwithstanding its ferocity in a state of nature, it is easily tamed when taken young, as we have elsewhere recorded of the specimen brought home in the Diamond frigate, by the late lamented Captain Lord Napier. The puma is more widely distributed than the preceding species, as it occurs not only over a great portion of South America, but extends northwards to the province of Pennsylvania, and even makes occasional inroads into the state of New York. For the history of the beautiful ocelot (*Felis pardalis*, Linn.), and of the other species of the New World, we must refer the reader to the works mentioned in the preceding note. In illustration of the genus, we have figured (see Plate VI., figure 3), the female of the chati (*Felis mitis*, F. Cuvier), a rare species, from South America. We have also represented[1] (see same plate, figure 6) another small species sent from India to the Edinburgh Museum. It exhibits an alliance to the lynxes in its slightly tufted ears.

In regard to the European feline animals, the only indigenous species (exclusive of the lynxes) is the common wild cat (*Felis catus*, Linn.), usually, though perhaps erroneously, regarded as the source of our domestic kind. A few lines may not be misbestowed on the subject of this curious inquiry. The opinion generally current amongst us, and even adopted by most naturalists, as to the origin of that useful domestic animal which we find as a reclaimed captive wherever man is in any measure civilized and gregarious, is, that it has sprung from the larger inhabitant of our rocky ravines and forests, a species of a brownish grey colour, paler beneath, marked with some deeper transverse bands, and three bars upon the tail, of which the lower part is blackish. Now several circumstances seem at variance with this supposition. The tail of the domestic cat is longer and tapers to a point,—that of the wild cat being of nearly equal thickness throughout, and thus appearing as if truncated at the extremity. The head, too, in the former is larger in proportion to the body.[2] All our other domestic creatures are larger than their original races, but the house-cat, supposing it to have sprung from the indigenous woodland species, seems to have reversed the rule; for never even its most pampered and overgrown condition does it in anyway equal the powerful dimensions of its supposed original.

When we seek to ascertain the origin of any anciently domesticated species, the mind naturally reverts to periods of antiquity, and to the history of nations characterized by remote records. It was from within the sacred precincts of the temples of Isis, and under the reign of the Pharaohs or Egyptian kings, that the earliest rays of science dawned upon the nations. There the heroic Greeks "drew golden light," and from thence were distributed, by more or less direct gradations, the knowledge and civilization which, long waning at the primal source with feeble and uncertain gleam, have burned like an unconsuming fire amid those "barbarian lands" to which they were conveyed. Egypt, so remarkable in the early civilization of the human race, might reasonably be supposed even *a priori* to have furnished the primitive families of mankind with one or more of its domesticated animals; and in relation more particularly to the present subject, we know that of all the ancient nations of whom we possess records, the Egyptians were the most noted for their appreciation of the useful qualities of the cat. It was even embalmed in their temples, in common with the mystical body of the ibis, and we doubt not it must have become familiar to them from its beneficial qualities as a domestic species; for the reverential regard in which several animals were held in ancient days may be supposed to have sprung either from the beneficial influence which they exercised in the economy of nature, or the more direct benefits which they conferred in the domestic state. That the people in question derived their cats from an indigenous source is more than probable, especially as a wild Egyptian species (*Felis maniculata*, Tem.) bears, of all others, the closest resemblance to the domestic breed. At all events, it could scarcely be drawn from the wild cat of Europe, as that species, though widely distributed over all the wooded countries of the continent, and ranging through Russia into Siberia, and over a great range of Asiatic territory, is unknown on the banks of the Nile, and seems to hold its centre of dominion rather in the temperate than the warmer regions of the earth. Another argument against the derivation of our domestic cats from the indigenous woodland species, may be drawn from the extreme scarcity of the former in the early ages of our history. It is known that in the time of Hoel the Good, King of Wales, who died in the year 948, laws were enacted to preserve and establish the price of cats and other animals remarkable for being alike rare and useful, and forfeits were exacted from any one who should kill the cat that guarded the prince's granary. Now, these precautionary regulations would seem to indicate that our domestic cats were not originally natives of our island, but were introduced from some of the warmer countries of the east, and required for a time considerable care and attention to preserve the breed. This would scarcely have been necessary had the original stock been found prowling in every thicket and *corrie* of the country, which the wild cat undoubtedly was in those distant days. We therefore agree with M. Temminck and other naturalists who suppose that the gloved cat of Northern Africa (*F. maniculata*) is the more probable source of our domestic kind (see Plate VI., figure 5). Its proportions agree generally with those of the wild cat of Britain, but it is smaller by about one-third, and its tail is comparatively longer and more slender. The nature of its coat and the distribution of its colours resemble those of the female wild cat, although it is more of a yellowish ash colour,—a hue, we may observe, which prevails in the natural tinting of many of the quadrupeds of northern Africa.[3]

---

[1] From *Naturalist's Library* (*Felinæ*), p. 232, pl. 25. It is figured in the work referred to as the *Felis ornata*, but it is described under the title of *Felis servalina*.

[2] Fleming's *British Animals*, p. 15.

[3] See Temminck's *Monographies*, p. 120, note, *Edinburgh Cabinet Library* (Nubia and Abyssinia, No. xii. p. 401), and Ruppel's work before referred to.

The last group of the feline genus of which we shall make mention includes the animals known under the name of *lynx*. They are chiefly characterized by the length of their fur, the comparative shortness of their tails, and their tufted ears. Their skins are of considerable value in commerce, and it appears that several species have been confounded by naturalists under the name of *Felis lynx*, Linn. The largest and most beautiful is sent to us from Asia by way of Russia. Its fur is of a reddish-grey colour, spotted with black. It equals a wolf in size, and is the *Felis cervaria* of Temminck. The lynx of the north of Europe (*Felis borealis*, Temm.) is of an ashy grey, varying to brown and hoary, the fur being extremely full. Naturalists are now inclined to recur to the opinion of Pennant, that the Canada lynx (*F. Canadensis*, Geoff.) and this species are identical. According to Sir J. Richardson, they are timid creatures, incapable of attacking any of the larger quadrupeds, but well armed for the capture of the American hare, on which they chiefly prey. They make a poor fight when surprised by a hunter on a tree; for though they spit like cats, and set up their hair in anger, they are easily killed by a blow on the back with a slender stick. They swim well, and will cross the arm of a lake two miles wide. Their flesh, which is white and tender, though rather flavourless, is eaten by the natives.

The lynx of temperate and southern Europe (*Felis lynx*, Temm.) has a red fur, spotted with brown. It has now almost disappeared from the more densely peopled portions of the continent. A specimen described by M. Bory St Vincent was, however, killed within eight leagues of Lisbon. It is rather frequent among the central and southern mountains of Spain, where it is said to attain a greater size and a more beautiful aspect than elsewhere. It is likewise well known in the Neapolitan dominions. We presume that this is the species which occurs in Germany, where, however, according to Tiedemann, it is now much rarer than of old. M. Schyntz informs us that it is by no means unusual in Switzerland. M. Delarbe mentions one that was killed in Auvergne in 1788, and Cuvier has recorded another destroyed at Barege, at a much later date. We are not aware that it exists at present in France, though it may no doubt still descend occasionally in search of prey from the more secure fastnesses of the Pyrenees. The south of Europe produces a distinct species of smaller size, described by Oken under the name of *Felis pardina*.

The caracal or Barbary lynx (*Felis caracal*, Linn., see Plate VI., figure 8), is a native of warmer and more southern climates than the preceding. It is a wild and savage animal, of a uniform wine red colour, about the height of a fox, but much more powerful. It has been known to attack and tear a hound in pieces. The caracal is probably the animal designated by the ancients under the name of lynx, as the species now distinguished by that title has never been found in those countries of which the lynx of the ancients was said to be a native. Pliny assigns Ethiopia as its original country, and according to Ovid,

> "Victa racemifero lyncas dedit *India* Baccho."

Several other species are described by naturalists. Of these we have here engraved the booted lynx of Bruce (*Felis caligata*, Temm., see Plate VI., figure 7), a wild animal extensively distributed over Africa, and also occurring, it is said, in Southern India.

TRIBE III.—AMPHIBIA.

The concluding tribe of the carnivorous Mammalia consists of the seals and morses. Their feet are so short, and so encompassed in the skin, as to render their terrestrial movements very awkward, but as the intervals of their toes are filled by membranes admirably adapted for natation, their swimming powers are nearly inexhaustible, and they pass the greater portion of their lives in water. The form of the body is elongated, the spine extremely flexible, the muscles very powerful, the fur short and close.

The genus PHOCA of Linnæus comprises a great amount, and a considerable diversity of species,—some of which, though still regarded as *seals*, are separated into minor genera by modern naturalists. The teeth differ considerably both in their nature and number, and when accurately ascertained and distinctly described, will no doubt aid the systematic observer in his arrangement of the species into natural groups. All the species agree in having five toes to both extremities. Those of the fore paws diminish in size from the what we may call the thumb to the exterior or little finger, while on the hind legs the lateral toes are the largest, and the others diminish towards the centre. The form of the head bears some resemblance to that of a dog, and in their natural cunning and intelligence, and their capacity of being tamed and instructed, they present a farther likeness to that sagacious creature. They prey chiefly on fish, and are extremely destructive to salmon and other migratory and gregarious species along our shores, in estuaries, and at the mouths of rivers. They seldom, however, ascend the fresh waters to any considerable distance from the sea, and the alleged occurrence of seals in remote Siberian rivers, and the inland waters of Lake Baikal, is a fact which requires confirmation.[1]

Although extensively distributed over the waters of the ocean, it is in high latitudes (whether northern or southern) that seals occur in greatest abundance,—such as inhabit tropical regions being as it were insulated from their kind, and occurring in less numerous assemblages. The species are so vaguely described by voyagers, and have been even as yet so indifferently characterized by naturalists, that their geographical boundaries are in no way well defined; but we may rest assured that those authors are in error who describe our northern kinds as occurring equally among the antarctic icebergs. All other animals have limits which they do not pass, and seals are doubtless subject to a corresponding restriction. For example, the gigantic species called the sea elephant (*Phoca proboscidea*, Desm.) is never found in the northern hemisphere, while such of the smaller southern species as have been examined, are found to differ from those of corresponding size, which are native to the European shores. In regard to the geographical distribution of marine amphibia, the views of Peron are deserving of consideration. He is of opinion that the species, in reference to their natural location, form three great geographical groups, of which two are northern (Atlantic and Pacific) and one southern, and that the species of each of these regions are proper to itself. He inclines to apply the same principles to the cetaceous tribes. In neither case, however, has he sufficiently considered the numerous species which occur in temperate and equatorial regions. A proper exposition of the species of the Mediterranean and the Euxine, and their comparison on the one hand with those of the north, and on the other with such as are known to occur in the enclosed waters of the Caspian, the Red Sea, the Persian Gulf, the Indian Ocean, and the frozen waters of the extreme south, would prove a subject of deep interest. It is indeed singular that animals so important in the scale of creation, whether we regard their great economic value to mankind, their position in the system of nature, or their peculiar organization and habits of life, should hitherto have attracted so superficial a notice on the part of naturalists.

---

[1] See Krachenninikow's *Voyage en Sibérie et au Kamtschatka*, t. ii. p. 421.

In the *restricted* genus Phoca (Peron), the external ear is obsolete or rudimentary; the incisives are pointed, with simple edges; the toes possess a certain degree of motion, and the claws by which they are terminated are placed on the margin of the uniting membrane.

Our common seal (*Phoca vitulina*, Linn., see Plate VII., figure 1) possesses, in common with the little group of species with which it is associated (*Calocephalus*, F. Cuv.), six incisive teeth above, and four below. It varies greatly in colour, and sometimes attains the length of six feet. It is frequent along the northern European shores, and extends into very high latitudes. It is even said to occur in the Caspian Sea, and the great fresh water lakes of Russia and Siberia; but this assertion, as Baron Cuvier has remarked, requires to be confirmed by an exact comparison of species. Seals were formerly used as food, though their flesh is coarse and dark coloured. Their blood is blackish, and very abundant. At present they are slain chiefly on account of their skins and oil. Dean Monroe informs us, that on the banks of Lochegrenord, in Islay, they were formerly killed by means of trained dogs. They seem occasionally subject to epidemic diseases. About fifty years ago numerous carcasses were cast ashore in every bay in the north of Scotland, Orkney, and Shetland, and many were found in a sickly state at sea.[1]

Our other British species is called the great seal (*Phoca barbata*, Fabr.). It attains the length of ten or twelve feet, and seems almost confined with us to the western and northern isles, although it has been occasionally met with off the Fern Isles, and a specimen was shot some time ago near Stonehaven by the late Lord Cassilis. It spreads, however, far and wide along the icy arctic shores.

Of the antarctic species we may name the small nailed seal, *Phoca leptonyx* of Blainville (genus Stenorhinchus, F. Cuv.), to which the species brought home by Captain Weddell from the South Orkneys, and now in the Edinburgh Museum, seems nearly allied.[2] The head of the latter is very small, the neck greatly elongated. Its teeth are, incisors $\frac{4}{4}$, canines $\frac{1-1}{1-1}$, molars $\frac{5-5}{5-5}$; $= 32$. The last named teeth are sharp, compressed, trilobate.

One of the most noted of the southern seals is the monstrous species so often mentioned by Dampier, Anson, Cook, and other navigators, under the names of sea lion, sea elephant, &c. It is the *Phoca leonina*, Linn. *Ph. proboscidea* of Peron and Desmarest, and probably also the *Ph. Ansonii* of the last named author, for its synonyms are almost as numerous as its own oily herds. It constitutes the type of the modern genus Macrorhinus, distinguished by having four incisive teeth in the upper jaw, and only two in the under, the molars obtusely conical, and the muzzle in the form of a short moveable proboscis. The species are widely extended over the southern hemisphere, and furnish the English and American fisheries with an important article of commerce. The sea elephant above alluded to is the largest of the group, attaining sometimes to the length of 30 feet, and measuring from 15 to 18 feet in circumference. The lower canines are long and projecting, and the male during the rutting season is characterized by the full inflated condition of the muzzle. It inhabits many of the desert isles and sandy shores of the southern hemisphere. According to Peron it migrates every season, with a view to avoid the extremes of heat and cold, moving southwards in summer and northwards in winter. Its favourite food consists of cuttle fish, and it loves to repose itself amid the thick and tangled beds of *Laminaria gigantea*. It is probable that it also feeds on fuci, as a quantity of marine vegetation has been found in its interior, mingled with the bones of cephalopodous mollusca. These animals keep much at sea during the first four months of the year, after which they pay frequent visits to the land. They move with great ease and some celerity in the water, but their motions on shore are slow and awkward, and they are then easily slain, notwithstanding their great strength and gigantic size. Their dispositions are naturally mild, their habits indolent, and their general character much less wary and mistrustful than that of the smaller tribes of seals. They are thus easily approached by man, and fall a ready victim to the lance of their pursuers. One male has generally several females, and, during the season of love, dreadful conflicts take place with a view to the formation of a seraglio. A certain degree of domestic peace is established in the autumn. Gestation continues about nine months, and the females bring forth one or two young ones in June of the ensuing year. At this period they usually assemble together on sandy flats, at some little distance from the shore, and surrounded by the males. They give suck for two or three months; during which time they are said to reside entirely on shore. They then descend together to the sea, where, after a few weeks' refreshment, they recommence their contentious courtships.[3]

We cannot here enter into farther details regarding the seal tribe, and shall conclude by observing that the *Phoca monachus* of Gmelin, a well-known Mediterranean species, common among the islands of the Adriatic, and the shores of Greece, and probably the species best known to ancient writers, belongs to the genus Pelagius of F. Cuvier, characterized by four incisors both above and below,—the molars being like obtuse cones, with a slightly developed heel before and behind.

The preceding groups of amphibious mammalia agree in the absence or rudimentary state of the external ear. It is otherwise, however, with the remaining genus Otaria, Peron, which is distinguished by *external ears*, and by the singular character of having double cutting edges to the four intermediate incisors of the upper jaw, the external being small and simple. All the molars are simply conical; the toes of the fore paws are almost immoveable; and the swimming membrane is prolonged in advance of the toes of the hinder extremities. All the claws are flat and slender. To this genus belongs the maned seal (*Phoca jubata*, Gmel.), or sea lion of Steller, Pernetty, and some other authors. It grows to the size of from fifteen to twenty feet, and the neck of the male is clothed with hair longer and more frizzled than that of the rest of the body. The species is usually described as occurring at both extremities of the Pacific Ocean, but the individuals found along the Patagonian coast, at the Malouin Islands, and in the Straits of Magellan, will assuredly be found to differ specifically from those of Behring's Straits and other northern regions. Forster describes them as living in troops, the old males roaring like lions or enraged bulls, and, except during the breeding season, living together apart from the females. On the Magellanic shores, they couple in December and January, carry eleven months, and bring forth two young. Those of Kamtschatka, according to Steller,[4] are of analogous habits; but in each group there are only two or three females, instead of ten or a dozen, and each produces at a birth only a single young. The flesh is held in some esteem by the natives of the Aleutian Isles and other northern tribes.

[4] *De Bestiis Marinis*, Mem. Acad. Petersb., t. ii.

To the preceding genus also belongs the Sea Bear, so called (*Phoca Ursina*, Gmel.). It measures about eight feet, and is destitute of mane. The colour varies with age and season, from brown to grey and white. The young, when newly born, are black. The fur of this species, when cleared of the longer coarser hair, is almost as much esteemed as that of the beaver. It fears the maned seal, but wages a cruel war against most other marine creatures. A corresponding species exists in either hemisphere, that is, the Ursine Seal is described by Steller as a native of Kamtschatka, and by Foster as inhabiting the southern coast of America, and the shores of New Holland, and Van Diemen's Land. It is probable that two distinct kinds are here confounded.[1] Various additional species are described by MM. Desmarest, F. Cuvier, Lesson, and other systematic writers.

Genus Trichechus, Linn. Incisors $\frac{2}{0}$, canines $\frac{1-1}{0-0}$, molars $\frac{5-5}{5-5}$; $=24$. Body elongated, and conical, like that of the preceding groups of seals. Head round, muzzle full. No external ears. Tail extremely short.

The absence of canine and incisive teeth from the lower jaw sufficiently distinguishes the present genus, which as yet contains but a single species, commonly called the morse, walrus, or sea-horse,—*Trichechus rosmarus*, Linn. See Plate VII., figure 2. It attains to the length of from 18 to 20 feet, and in its general aspect and habits resembles a gigantic seal. It is an animal of gregarious disposition, and occurs abundantly in the Northern Atlantic, and the polar regions of the Pacific Ocean. The walrus is sought for amid those icy solitudes, on account of its oil, skin, and ivory tusks. The latter are harder and more homogeneous than those of the elephant, and are less apt to be rendered yellow by the hand of time, for which reason they are useful to dentists in the fabrication of false teeth. The capture of this animal is not, however, an object of such importance as it is known to have been prior to the institution of the Spitzbergen whale-fishery. In fact, it is now allowed to float along its desolate shores, almost without molestation from the British, the Russians being its principal persecutors. Our whale-fishers seldom take more than half a dozen in a voyage, although the elder Scoresby once procured in a single season 130 in Magdalene Bay. But this is nothing to the multitudes obtained in former times. Stephen Bennet, for example, in 1606, along the shores of Cherry Island, killed 700 or 800 in less than six hours; and in the ensuing voyage about 1000 were slain in less than seven hours. "When seen at a distance," says the Rev. Dr Scoresby, "the front part of the young walrus, without tusks, is not unlike the human face. As this animal is in the habit of raising its head above water, to look at ships, and other passing objects, it is not at all improbable but that it may have afforded foundation for some of the stories of mermaids. I have myself seen a sea-horse in such a position and under such circumstances, that it required little stretch of imagination to mistake it for a human being; so like indeed was it, that the surgeon of the ship actually reported to me his having seen a man with his head just appearing above the surface of the water."[2] The walrus is a fearless animal, paying no regard to a boat, except as an object of curiosity. Its capture in the water is not made without danger, as an attack on one individual generally draws its neighbours around it, and the planks of the boat are sometimes pierced with their tusks, which, from the great weight of the suspended body, become weapons of enormous power. The species is confined to the coldest regions of the northern hemisphere, and its southern boundary is probably more restricted than of old. It is mentioned by some of our ancient native writers, but has been long unknown along the British shores, although the ivory bits described by Strabo as articles of British commerce may be conjectured to have been fabricated from its teeth. In December 1817, a solitary wanderer, who had probably been floated southwards on an iceberg, was shot while reposing on a small rock in the Sound of Stockness, on the east coast of Harris, one of our Outer Hebrides.[3]

Order III.—MARSUPIALIA.

The order which contains the marsupial or pouched animals, is composed of such heterogeneous elements, as to be extremely difficult of definition. The most universal, as well as remarkable peculiarity, consists in the premature production of the young, the majority of which are born in a state comparable only to that exhibited by the fœtus of other animals not many days after conception. Thus the Virginian Opossum, when first brought forth, does not weigh above a single grain, though its parent is as large as a full-grown cat; and the Gigantic Kangaroo, which sometimes attains the weight of nearly 200 pounds, gives birth to a pair of young ones, each about an inch long. Incapable of voluntary movement, destitute of distinct sensation, and with the external organs in a rudimentary state, the feeble offspring becomes attached (in a manner as yet but indistinctly known) to the mammæ of the mother, and adheres to them continuously till such time as it has attained the ordinary conditions of a new born creature, and even long after that period it continues to seek frequent refuge in its parent's lap, which for that purpose is furnished with an ample pouch, within which the nipples are contained. Two special bones attached to the pubis, and interposed between the muscles of the abdomen, support the pouch, and occur at the same time not only in the females of certain species in which the pouch is scarcely perceptible, but also in the males, in which it does not exist.[4] Another peculiarity of the marsupial order consists in this, that in spite of a general resemblance which so strikingly pervades the species, that for a long time they were regarded as forming only a single undivided genus, they differ so greatly in their teeth, and in their organs of digestion and of locomotion, that a rigorous adherence to these characters, would induce their partition into various orders. "On disait, en un mot," says Baron Cuvier, "que les marsupiaux forment une classe distincte, parallèle à celle des quadrupèdes ordinaires et divisible en ordres semblables; en sorte que si on plaçait ces deux classes sur deux colonnes, les Sariques, les Dasyures, et les Peramèles seraient vis-à-vis des carnassiers insectivores à longues canines, tels que les tenrecs et les taupes; les Phalangers et les Potoroos, vis-à-vis des herissons et des Musaraignes; les Kanguroos proprement dits ne se laisseraient guère comparer à rien, mais les Phascolomes devraient aller vis-à-vis des rongeurs. Enfin, si l'on n'avait égard qu'aux os propres de la bourse, et si l'on regardait comme marsupiaux tous les animaux qui les possèdent, les ornithorinques et les echidnés

[4] "La matrice des animaux de cette famille n'est point ouverte par un seul orifice dans le fond du vagin, mais elle communique avec ce canal par deux tubes latéraux en forme d'anse. Il parait que la naissance prématurée des petits tient à cette organization singulière. Les mâles ont le scrotum pendant en avant de la verge, au contraire des autres quadrupèdes, et la verge, dans l'état des repos, est dirigée en arrière." *Règne Animal*, t. i. p. 173.

Marsupialia.

y formeraient un groupe parallèle à celui des édentés."[1] In these views we can scarcely agree, and in truth they have not been proceeded upon by their author, who, in his most recent work, continued to group the marsupial genera under a distinct order, as above named.

Many years have elapsed since (in 1828) we ventured to express our opinion regarding the unnatural constitution of the marsupial order, and we are satisfied to see that similar sentiments have been generally expressed in more recent times. The present work does not present a proper field on which to enter into a minute detail of the many ingenious, though not always consistent, theories which have been proposed in explanation of the numerous anomalies observable in the structure and habits of this extraordinary assemblage of living creatures. Considered even in regard to their external structure, something remarkable may be presumed to characterize a group of animals regarding the division and arrangement of which scarcely two naturalists of note have expressed the same opinion. Baron Cuvier, as we have seen, made them constitute the fourth family of his Carnivorous Order; MM. Geoffroy St Hilaire and Latreille regarded them as forming of themselves a separate order, while M. De Blainville erected them into what he was pleased to call a sub-class of the animal kingdom. In fact, as we have already observed, the only principle on which zoological writers were formerly of one mind in relation to the Marsupialia, was that of holding the genera together in juxtaposition,—certainly an unfortunate principle to proceed upon, if it can be shewn to be inconsistent with the due consideration of those natural and undisputed analogies by which we profess ourselves to be guided in our arrangements of the other tribes. It has been well observed, that the marsupial genera exhibit the types of almost as many separate orders as exist among all the other Mammalia; and no one will doubt of this being in a great measure true, who has ever examined the well armed jaws of a Didelphis or Dasyurus, and compared them with the simple structure of the same parts in the gentle wombat.

According to the principles of the natural system so much (and deservedly) insisted on by the modern school, the group of genera named MARSUPIALIA, whether regarded as a family or an order, includes indeed such heterogeneous elements, as bid defiance to every preconceived form of classification. It is true that they all present some peculiar modifications of the generative and lacteal systems; and if the student has recourse to these alone, and regards them as a sufficient and satisfactory basis for the establishment of a primary character, in conformity with the nature of which the totality of the class Mammalia is to be partitioned into two great subdivisions, then the *Monodelphs* and *Didelphs* of M. De Blainville may suffice. But if the formation of a *class*, according to the admitted signification of the term, depends upon the coexistence of certain characters, neither few in number, nor of less than the highest value and importance in their kind, it is difficult to see why the mere existence of an external pouch, or duplication of the abdominal skin, though connected with a very peculiar, and it may be unaccountable mode of fœtal production, should suffice for the establishment of one of the greatest divisions of which the animal kingdom is regarded as susceptible. A bird differs in its class from a mammiferous animal or quadruped commonly so called, on the one hand, and from an amphibious animal or reptile on the other; and it is distinguished from both by many essential organic attributes, which involve such a difference in the vital functions and economy of the several subjects of these different classes, as to render their mutual discrimination, as it were, apparent to the most cursory observer. They not only differ in their mode of producing their young, and in their method of rearing it, but also in the structure of the heart, the character of the respiratory and circulating systems, the perfection of the senses, the number of the cervical vertebræ, and consequently in their whole external form and aspect. But the marsupial animals, however dissimilar to each other, do not vary essentially from certain types which occur in one or other of the numerous orders of which the *normal* mammalia are composed; and with these different genera they may assuredly be combined, in a manner more consistent with the principles of the natural system, than when they are allowed to constitute by themselves a separate and exclusive division, by whatever name it may be called. "Let each of the marsupial genera be classed according to the position pointed out by a careful study of its natural and most influential characters; and if, for example, the structure of its teeth indicate a carnivorous disposition in one genus, an insectivorous one in another, or a herbivorous one in a third, then let each be referred to its appropriate station in the general system, whether as a member of the Carnivora, the Insectivora, or in closer connection with the more harmless Glires. But do not re-establish the worst parts of an artificial method, by following a fanciful analogy in the structure of a secondary and apparently uninfluential organ. That the marsupium or pouch is not a character of a highly influential kind, is evident from its occurrence in tribes and genera which in every other respect are so variously and dissimilarly constituted. It does not, in short, afford a key to the rest of the organization."[2] The preceding observations may suffice to guard the reader from the supposition that the Cuvierian order of marsupial animals is of natural component parts We adhere, however, to that order, in conformity with our adoption of the general principles of classification laid down in the *Règne Animal.* The Marsupialia are arranged by Owen into five varieties, according to their digestive organs.

Marsupialia.

These tribes appear to be confined entirely to New Holland, America, and one or two islands in the eastern seas. They are unknown in Europe, Africa, and continental Asia. We shall now proceed to a brief notice of the genera.

DIVISION I. Long canines and small incisors in both jaws. Abdominal pouch sometimes wanting.

The hind molars of this group are beset with points, and in general all the characters of the teeth are those of the insectivorous tribes, to which they consequently approximate closely in their food and habits.

GENUS DIDELPHIS, Linn. Incisives $\frac{10}{8}$, canines $\frac{1-1}{1-1}$, molars $\frac{7-7}{7-7}$ or $\frac{6-6}{7-7}$; = 50 or 48. Head long and conical. Muzzle pointed. Mouth deeply cleft. Eyes placed high, oblique. Ears large, thin, nearly naked, rounded in their outlines. Tongue ciliated on the edges, and beset with horny papillæ. Five separate toes to each foot. The thumb of the hinder extremities (which are plantigrade) opposable, and destitute of nail; the nails of the other toes curved. Tail rather long, round, scaly, and without hair throughout the greater part of its extent. Stomach small and simple; cœcum of medium size, not pouched.

This genus contains the most anciently known of the marsupial tribes, and is peculiar to America, particularly the southern division. The species are known under the general name of opossums. They are nocturnal animals, resembling martens in their habits, but are less active in their movements. Their intelligence is limited, a fact in curious conformity with the entire absence of all folds or convolutions of the brain,[1] and according with the theory of M. Desmoulins, that the intellectual faculties are in the direct ratio of the extent of the cerebral surfaces.[2] They dwell in woods, where they climb the branches of trees, feeding on birds, eggs, reptiles, insects, and fruits. They enter farm-yards, and commit great damage by sucking the blood of poultry.

---

[1] *Loc. cit.* p. 174.

[2] Wilson's *Illustrations of Zoology*, vol. i. Order Marsupialia.

One of the best known is the Virginian opossum, Plate VII., figure 3 (*Didel. Virginiana*, Penn.) It exists over a great extent of territory from Paraguay to the country of the Illinois, and is well known in the southern United States. This species lives in fields and woods, and often enters houses during the night, in search of domestic birds, or other prey. It brings forth upwards of a dozen young at a time, which at first do not weigh above a grain. They instinctively adhere to the teat, to which they continue fixed till they are as large as mice, and become covered with hair. The first gestation lasts about six-and-twenty days, and the offspring remain in the pouch for nearly twice that period. Azara has seen them carried along by their mother, by means of their little tails twisted round that of their parent.

The crab-eating opossum (*D. cancrivora*, Gmel.) is a more restricted species. (See Plate VII., figures 5 and 5 *a*.) It inhabits the coasts of Guiana and Brazil, and besides the usual prey, is said to feed greedily on crabs, which, according to Laborde, it catches by introducing its tail into their holes. Several other species are described by naturalists.

GENUS THYLACINUS, Temm. Distinguished from the preceding by the want of thumb on the hinder extremities, the tail covered with hair and not prehensile, and two incisors less in each jaw. The ears are of moderate size, and haired.

This genus has been instituted for the reception of a single species from Van Diemen's Land, described by Mr Harris, under the name of *Dasyurus cynocephalus*.[3] It is the *Thylacinus Harrisii* of Temminck.[4] This animal is as large as a wolf, though somewhat lower in the legs, and may be regarded as the strongest and largest of all the flesh-eating species of Australia. It is of a greyish colour, with transverse bands of black on the hinder parts of the body. The head is large, and resembles that of a dog. It dwells among rocks and caverns, in the deep and almost inaccessible glens in the vicinity of the highest mountains of its native island, and is said to prey upon the brush kangaroo and other quadrupeds. Some authors allege that it feeds on Ornithorhynchi, Echidnæ, and crabs, and that its compressed tail gives it great power and activity as a swimmer But we find nothing of this kind given by its original describer, who does not even mention it as a littoral species, although M. Temminck, and in his wake subsequent compilers, make it inhabit rocks by the sea shore. It may do so, but the fact is not stated by Mr Harris.

As we cannot detail the characters of all the minor marsupial groups, we may here note that the *Didelphis penicillata* of Dr Shaw, and the *Dasyurus minimus* of Geoffroy, form the genus PHASCOGALE of Temminck.

GENUS DASYURUS, Geoff. Incisives $\frac{8}{4}$, canines $\frac{1-1}{1-1}$, molars $\frac{6-6}{6-6}$; $= 42$. Anterior feet with five toes, armed with curved claws, the posterior with four, and a fifth in a rudimentary state, without nail, and distant from the others.

The Dasyuri approach the opossums (*Didelphis*) in their general organization, but wanting the strong thumb of the hinder extremities, and the tail being not prehensile, they are incapable of climbing trees like their American congeners. They prey chiefly during the night, feeding on small quadrupeds, birds, insects, mollusca, and the remains of seals or other marine animals which they may occasionally find along the shore. The species (at present four in number) are restricted to New Holland and Van Diemen's Land. We may mention as an example the *Das. ursinus* of Temminck (*Delph. ursina*, Harris), an animal of subterranean habits, extremely common at the time of our first settling at Hobart Town, where it proved particularly destructive to poultry. It, however, in return frequently furnished the convicts with a fresh dinner, and its flesh was said in taste to resemble veal. As the settlement increased they retired to the deeper recesses of the forest, where they are still easily procured by traps, baited with any kind of raw meat. Their tracks are often seen on the sea shore.

GENUS PERAMELES, Geoff. Incisors $\frac{10}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{7-7}{7-7}$; $= 48$. Head elongated, muzzle pointed. Feet with five toes, of which the fore paws have the innermost and outermost merely rudimentary, and without nails, and the middle toe the largest. The hind feet have the thumb or innermost toe rudimentary, and without nail, the second and third united under a common integument as far as the nails, the fourth the largest and most elongate, and the fifth or outer toe next in size to the preceding.

Although systematic writers describe three species of this genus, the only one as yet distinctly known is the long-nosed perameles (*P. nasuta*, Geoff.), or pouched badger of New Holland, an insectivorous animal resembling a large brown rat in its external aspect. (See Plate VII., figures 4, 4 *a*, and 4 *b*.) One of the most remarkable characters detected in a specimen submitted to our examination many years ago by Professor Jameson, consisted in this, that the marsupium, or abdominal pouch for the reception of the fœtal young, did not open from above downwards, as in most other marsupial animals, but commenced almost imperceptibly at the distance of half an inch from the anterior margin of the anus, and extended upwards beneath a thick fold of the skin as far as the sternum,—the entrance of the sack being arched upwards, and quite open for more than an inch from its lower or posterior margin. The whole cavity was lined with soft, very short, white, woolly hair, and its parietes were remarkably soft and dilatable.[5]

DIVISION II. Two long incisives in the lower jaw, projecting forwards. Six incisives in the upper jaw. The upper canines, as usual, long and pointed, but the lower so small as to be frequently hidden in the gums. Thumb of the hinder extremities separate and opposable, the two following toes shorter than the others, and united as far as the toes. The intestines and the cœcum long. An abdominal pouch in all the females.

The regime of this division, as might be inferred from the structure of the teeth and intestines, is almost entirely frugivorous.

GENUS PHALANGISTA, Cuv. The Phalangers properly so called, exhibit no extension of the skin along the flanks. They have in each jaw four posterior molars presenting a double range of points, besides a large anterior tooth compressed and conical, between which and the upper canine teeth are two others small and pointed. To the latter correspond the very small teeth of the under jaw already mentioned in the divisional character. The tail is prehensile.

[3] *Linn. Trans.* vol. ix. pl. 19.

[4] *Monog. de Mamm.* t. i. p. 60.

[5] See the detailed observations with which we were kindly furnished by Dr Grant (of the London University), and published in the first volume of our *Illustrations of Zoology*.

The species inhabit the Moluccas, New Holland, and Van Diemen's Land. They in some measure represent in the ancient world the opossums of America, but they differ greatly in their teeth. Those of the Moluccas and other eastern islands dwell in trees, and feed on fruits and insects. Their flesh is eaten, though it exhales a disagreeable odour. The tail is naked and scaly. M. Temminck distinguishes five species,—*Phal. ursina, chrysorrhos, maculata, cavifrons*, and *Quoy*. In the Australian species, the tail is furred. The latter amount to three,—*Phal. vulpina, Cookii*, and *nana*, Temm.[1]

In the genus PETAURUS of Shaw, which includes those animals commonly called flying Phalangers, the skin of the sides is more or less extended. By this structure they are partly supported in the air, so that their leaping powers are greatly increased. They are peculiar to New Holland. In some of the species, canine teeth still exist in the lower jaw, but extremely small in size. The upper canines, and the first three molars, both above and below, are very pointed. The posterior molars have each four points. As an example, we may name the pigmy opossum of Shaw (*Pet. pygmæa* of Desmarest, who of this group forms his subgenus of *Voltigeur* or *Acrabata*), one of the smallest of quadrupeds, scarcely exceeding a mouse in size. The hairs of the tail are beautifully disposed on either side, like the barbs of a quill. (See Plate VII., figures 7 and 7 *a*.) Other species want the lower canine teeth, and the upper ones are very diminutive. The four hinder molars also present four points, but somewhat curved or lunate, in which they approximate those of the ruminants. There are two additional anterior molars above and one below, of a less complicated character,—a structure which, as Cuvier observes, renders the species more frugivorous than the preceding.

DIVISION III. Two long projecting incisors in the lower jaw and six in the upper. Canine teeth in the upper jaw only. Hinder paws long and narrow, without thumb, the first two toes being very small, and united together as far as the base of the nails. An abdominal pouch in the females.

The only genus of this division is that called *Hypsiprymnus* by Illiger, consisting of the kangaroo rat, *Hyp. murinus*, Desm. (*Macropus minor*, Shaw). It has on each side of both jaws a long-shaped anterior molar, cutting and dentated, followed by four others beset by four blunt tubercles. There is only a single species known, of a mouse colour, equalling a small rabbit in size. Its regimen is herbivorous, its stomach large, divided into two sacks, and much pursed. The cœcum is rather small and rounded. This animal is called potoroo by the natives of New Holland.[2] The great length of its hinder extremities indicates its leaping powers.

DIVISION IV. No canine teeth in either jaw.

GENUS MACROPUS, Shaw, Cuv. *Halmaturus*, Illiger. *Kangurus*, Geoff. Desm. Incisives $\frac{6}{2}$, canine $\frac{0-0}{0-0}$, molars $\frac{5-5}{5-5}$; $= 28$. Extremities disproportioned, the fore legs being small, short, and furnished with five toes; the hinder legs, much lengthened, and muscular, with only four toes, of which the two inner are very small and united together. Tail lengthened, strong, furnished with powerful muscles, and of great use in locomotion. Hair woolly. An abdominal pouch in the female.

This singular genus, of which nearly a dozen species have been described by voyagers and systematic writers, contains the animals commonly called kangaroos. "Buffon, whose only errors were those of genius, clearly perceived that every continent, in its animal productions, presented the appearance of a special creation; but he gave an universality to this proposition, of which it is not altogether susceptible. It is nevertheless true, even at the present day, within certain limits. A great number of the Asiatic animals are not found in Africa, and *vice versa*. The lemurs seem to exist only in Madagascar. America is peopled with a host of mammalia exclusively peculiar to itself, and there are many more in Europe not to be found in the other quarters of the globe. The discovery of Australia has given an additional support to the opinion of Buffon. The species of animals there discovered have not only no affinity with those of the other continents, but, in fact, belong, for the most part, to genera altogether different. Such are those mammalia which the natives of New Holland call kangaroo, and which offer to the observation of the naturalist organic peculiarities perceivable in no other animal, with the exception of a single species. It is in this tribe that, for the first time, we view the singular phenomenon of an animal using its tail as a third hind leg in standing upright and in walking."[3]

Kangaroos in general dwell in small troops of from twelve to thirty, under the guidance of an old male. In a state of repose they rest as it were upon a kind of tripod, composed of the two hinder legs and tail, the body being nearly perpendicular, and the head extended horizontally. In moving leisurely they employ their fore feet like other quadrupeds, but, in more rapid progression, they advance by prodigious bounds, leaping, it is said, nearly thirty feet at a single spring. MM. Quoy and Gaymard, however, who often hunted these animals, inform us, "que lorsqu'ils etaient vivement poursuivis par les chiens, ils couraient toujours sur leurs quatre pieds, et n'executaient de grands sauts que quand ils rencontraient des obstacles à franchir." The support which they receive from their tails is also of great advantage in self-defence, by enabling them to inflict severe wounds with their hind feet. In the natural state their habits are herbivorous, but in a domestic condition they eat almost every kind of food. Their own flesh is held in considerable estimation, and as they now breed freely in this country, the time may come when we shall find a joint of kangaroo an acceptable and frequent dish upon our own tables. The females bring forth only one or two at a time.

One of the largest species of the genus is that described in Cook's first voyage. It is the *Macropus major* of Shaw (*Kangurus labiatus* of Desm.), and is distinguished by its fur of an ashy grey colour above, paler below, a transverse band of grey upon the chin, the upper surface of the legs and tail being of a blacker hue. It measures nearly six feet in height, and is well known in the neighbourhood of Botany Bay. Mr Cunningham probably alludes to the hunting of this species in the following passage:—"From the great length of their hind legs and tail, they are enabled to stand on the firm bottom, while the dogs are obliged to swim, and in this way a fight between a large kangaroo and a pack of dogs affords a most amusing spectacle. The kangaroo stands generally upright, with his fore paws spread out before him, wheeling round and round to ward off his assailants; and whenever one arrives within reach, he pounces his paws upon him, and, sousing him suddenly under, holds him fast in this position, gazing all the while around with the most solemn simpleton sort of aspect, heedless of the kicking and sprawling of his victim, whom he quickly puts an end to, if some courageous colleague does not in good time advance to aid, and force the kangaroo to let his half-drowned antagonist bob above water again, who paddles forthwith toward shore, shaking his ears and looking most piteously, with no inclination to venture in a second time, notwithstanding all the halloos and cheerings with which you urge him."[1]

---

[1] The last named species is not inserted in the second edition of the *Règne Animal*, but another is described under the name of *Phal. Bougainvillii*. For the descriptions, see *Monograph. de Mammalogie*, p. 1.

[2] White's *Voyage to New South Wales*, p. 286. Philip's *Voyage to Botany Bay*, p. 277. M. F. Cuvier is of opinion that the observations of MM. Quoy and Gaymard have established the existence of other species besides the kangaroo-rat above named. To the latter they give the name of *H. Whitei*. It is probably identical with *Kangurus Gaimardi* of Desmarest.

[3] Griffith's *Animal Kingdom*, vol. iii. p. 47.

The preceding is sometimes confounded with a still larger species, called the sooty kangaroo (*K. géant* of F. Cuvier), which inhabits the south coast of New Holland, and is supposed likewise to occur in the vicinity of Port Jackson. The latter is seen in large troops, which, in the course of their habitual movements, form broad well-beaten footpaths, which a stranger would readily mistake for those occasioned by a numerous and active colony of the human race. Another species, called the banded kangaroo (*K. fasciatus*, Peron and Lesueu),[2] inhabits the islands (Bernier, &c.) on the west coast of New Holland. Its ears are smaller, and its tail feebler, than the same parts of the other species. It dwells among almost impenetrable thickets of a low growing species of mimosa, through which it forms numerous galleries, communicating with each other, and in which it seeks refuge on the approach of danger. From these and other peculiarities in its form and habits, M. Fred. Cuvier regards it as the type of a genus distinct from *Macropus*, and on which he bestows the name of *Halmaturus*, originally proposed by Illiger for the kangaroos.[3] We think it unnecessary to extend our observations on animals, the general habits of which have of late years been so frequently described, and shall merely name Le Brun's kangaroo (the Javan opossum of Pennant and Shaw, *K. Brunii*, Desm.) as a species which occurs somewhat beyond the range of its nearest allies. It inhabits the Aroe Islands, and, according to Le Brun, digs in the earth like a rabbit.[4]

Division V. Two long incisive teeth in the under jaw, no canines; two long incisives in the middle of the upper jaw, with some smaller lateral ones, and two small canines.

Here naturalists place only a single species, the *Phascolarctos fuscus* of Blainville, commonly called the *Koala*. Besides the teeth mentioned in the preceding divisional character, this animal has four molars on each side of both jaws, making twenty-eight teeth in all. Its feet are pentadactylous.[5] Its ears large and pointed, with the conch directed forward. The limbs are short, and the tail wanting. It somewhat resembles a bear in its aspect, and is said both to climb trees with facility and to burrow in the ground. The female carries about her young for a long time upon her back. The koala attains the dimensions of a middle-sized dog, and inhabits the banks of the river Vapaum in New Holland.

Division VI. Two cylindrical truncated incisives in each jaw. No canines.

This division, like the preceding, contains only a single species commonly called the Wombat, which constitutes the genus *Phascolomys* of Geoffroy and Cuvier. In addition to the teeth above mentioned, there are five molars in each side of both jaws, or twenty-four teeth in all. The wombat is about the size of a badger, and, in its general aspect, resembles a small bear. In its dentition and intestines it is closely allied to the order Rodentia, which we are now about to enter; but the articulation of the lower jaw is different. Its habits, however, are herbivorous. Captain Baudin introduced two specimens into the French Menagerie from the south coast of New Holland. Their motions were slow, their dispositions gentle and passive; and though tame, so far as the absence of fear was concerned, they exhibited little sense or discrimination. In their natural state they live in burrows, and the female brings forth three or four young at a birth. Peron stated that the flesh of the wombat is much esteemed by the seal-fishers, and Cuvier expressed his desire that it should be naturalized in the *basse-cours* of France, as likely to prove a valuable addition to the table. It is the *Phasc. wombat* (see Plate VII., figure 6) of Peron and Lesueur,[6] the *Phasc. Bassii* of Lesson,[7] and the *Wombatus fossor* of Geoffroy.[8] Some confusion has arisen in its history in consequence of Bass (and we believe also Flinders) having described under the name of wombat, an animal of corresponding external aspect, but furnished with six incisives, two canines, and sixteen molars in each jaw. The latter has by some been referred to the genus *Phascolarctos*, with which, however, its dentition is equally discordant. We know, in truth, little of the animals (whether of one or more species) hitherto recorded under the title of wombat, except that they are feeble defenceless creatures, inhabiting certain islands in Bass's Straits.[9] They seem to have been first noticed by Dr Shaw, in his crude compendium, under the name of *ursine opossum*,[10] and a good deal has been since written about them to very little purpose. Mr Bennet, however, informs us, that a wombat was kept alive, and in a tame state, at Been, in the Jumal country. It usually remained in its habitation till dark, and then came out in search of the keelers or milk vessels, from which it would contrive to get off the covers, and would then bathe itself in the milk, drinking at the same time. It would also enter the little vegetable garden attached to the station, in search of lettuces, to which it evinced great partiality; and when none could be found, it would gnaw the cabbage stalks without touching the leaves.[11]

Order IV.—GLIRES or RODENTIA. GNAWERS.

The following are the principal characters of this extensive order. Two large incisive teeth in each jaw, separated by an empty space from the molars. No canine teeth.

---

[1] *Two Years in New South Wales*, vol. i. 314.

[2] *Voyage aux Terres Australes*, i. 114.

[3] We fear he has bestowed this name of *Halmaturus* (ἅλμα, saltus, οὐρη, cauda) on the species which it least befits.

[4] *Voyage aux Indes*, p. 374, pl. 213. See also Gould's *Mammals of Australia*.

[5] In relation to this character authors differ. "Le pouce manque au pieds de derrière," Cuv. *Règne Animal*, t. i. p. 188. "Le pouce des extrèmités postèrieures très gros, separé, sans ongle," Desm. *Mammalogie*, p. 276. We have never ourselves seen a koala.

[6] *Voyage aux Terres Australes*, pl. 58.

[7] *Manuel des Mamm.* p. 229.

[8] *Ann. Mus.* t. ii. p. 364.

[9] Naturalists differ even in their simple observation of the form of the intestines. The cœcum, according to Geoffroy, is very small and slender, while Cuvier describes it "gros et court." It is furnished with an *appendix vermiformis*.

[10] *General Zoology*, vol. i. p. 504. Its anatomy described by Sir E. Home in *Phil. Trans.*

[11] *Wanderings*, vol. i. p. 330.

Molar teeth either with flat crowns, or with more or less of a tuberculated surface. The four extremities terminated by unguiculated toes, which vary in number according to the species. Thumb sometimes rudimentary or obsolete; never opposable to the other toes. Number of mammæ various. Orbits not separated from the temporal fossæ. Lower jaw articulated by a longitudinal condyle. Hinder extremities exceeding the anterior in length. Stomach simple; intestines very long; cœcum large, but sometimes wanting.[1]

The genera of this order confine themselves chiefly to a vegetable diet, by which we mean not only leguminous plants, but grain, grasses, fruit, nuts, and other productions of the earth. They derive their name of gnawers from their mode of eating, which consists in reducing their food by a continuous action of the front teeth, into very small particles, instead of tearing it like the carnivorous tribes, or grinding it by a lateral motion, like the ruminating ones. In the Rodentia, the lower jaw is so articulated as to admit, in addition to the vertical movement which must necessarily obtain in all the higher animals, of a motion backwards and forwards, but not lateral; and in fine adaptation to this structure, the raised plates of the molar teeth are placed transversely, so as to act in more direct opposition to the confined horizontal movement of the jaw, thus aiding the power of trituition. A few of the species (such, for example, as the earless marmot, *M. citillus*, Linn.), are somewhat carnivorously inclined, and in natural accordance with this propensity, their molar teeth are jagged, or more sharply tuberculated than in other genera. Several of the murine species may be said to be omnivorous, and have become colonized in many foreign regions, through the unintentional agency of man. Most of the hybernating quadrupeds belong to this order. The Rodentia seem to inhabit all parts of the known world, with the exception of the numerous islands which compose the different central archipelagoes of the South Seas, where they do not occur as aboriginal. They are creatures of a timid disposition,—their habits for the most part nocturnal.

DIVISION I. With clavicles.

GENUS SCIURUS. Linn. Cuv. Incisors $\frac{2}{2}$, canine $\frac{0-0}{0-0}$, molars $\frac{5-5}{4-4}$; $= 22$.[2] Anterior paws with four toes, furnished with curved compressed claws, thumb tubercular; posterior paws with five toes, which, as well as the tarsus, are elongated. Tail long, usually furnished with an ample fur of considerable length. Two pectoral and six ventral mammæ.

The species of this genus, commonly called Squirrels, are with few exceptions essentially arboreal in their habits, and pass their lives among the umbrageous branches of forest trees, where they construct a spherical nest, composed of twigs, leaves, and moss, intermingled occasionally with a portion of fur apparently plucked from their own bodies. Certain species, however, inhabit burrows at the base of trees. Squirrels are extensively distributed over the whole earth, with the exception of New Holland, where as yet none has been discovered. Buffon was in error when he supposed the species in general to be characteristic of the colder and temperate regions of the earth; for we now receive many fine kinds from the warmest countries of Asia, and the sultry forests of Africa are by no means unproductive of these agile tribes. The species, however, are much more abundant in North America than in Europe.

The distichous or divergent character of the fur upon the tail, and the absence or existence of cheek pouches, furnish characters by which the genus is divided into minor groups.

Of those with distichous tails, but unprovided with cheek pouches, our common squirrel (*Sciurus vulgaris*), affords a familiar example. This beautiful and active creature is widely dispersed over the cold and temperate zones of the ancient continent, and its external colour and aspect vary with the diversified climates under which it occurs. Several imaginary species have been described by travellers not conversant with the modifications which it undergoes. In Britain, France, and Southern Germany, the fur is always of a reddish-brown above, more or less lively according to the season, and of a pure white below. In the northern parts of Europe and Asia, it assumes a much grayer hue in winter, owing to the hairs becoming encircled with whitish rings. A black variety is described by Pallas and Gmelin as native to the rugged and mountainous regions which surround Lake Baikal; but it is more than probable that it will be found to constitute a distinct species. The common squirrel does not hybernate or become torpid during winter, but stores up in the trunk of a tree a supply of nuts, acorns, pine seeds, &c., to which it has recourse, when the ordinary supplies of the forest have fallen or been exhausted. Its graceful and varied postures, with its beautifully flowing tail, its sparkling eyes and tufted ears, its activity and cunning in a state of nature, and familiar petulance in confinement, are all too generally known to need description. It never breeds in captivity. The only other European species with which we are acquainted is the *Sciurus alpinus* of M. F. Cuvier, a native of the Alps and Pyrenees. In its general size and proportions it resembles the common kind, but its head is somewhat less. Its colour is deep brown, speckled with yellowish-white above, the under parts being pure white. The inner surface of the limbs is grey; the edges of the lips are white. A fulvous band separates the white and grey of the under parts from the brown of the upper. A male and female lived for a long time in the Menagerie of the French Museum, and the colours of their coat underwent no change, further than that the brown became somewhat blacker in winter, and that the tail, during the latter season, assumed a greyer aspect.[3] For the numerous foreign species we must refer the reader to the works of systematic authors. We have figured as an example of the genus, the *Sciurus cinereus* of America. (See Plate VIII., figure 1.)

The *flying squirrels* belong to the genus PTEROMYS of Cuvier, and are characterized by an extension of the lateral skin, which spreads out from the fore to the hind legs, and, by acting as a parachute, greatly aids them in the act of leaping. A species (*Sciurus volans*, Linn. *Pt. Sibiricus*, Desm.), occurs in Poland, Russia, and Siberia. It feeds chiefly on the young shoots of pine trees, and, according to Pallas, its excrements thus acquire so resinous a quality, that they burn with a pure bright flame. It springs from branch to branch and from tree to tree with the most surprising agility. It is not readily tamed, and bites severely when in a state of irritation. Another flying squirrel (*Pt. volucella*, Desm.), erroneously named *polatouche* by Buffon, from the Russian name *polatucka* (which applies to the preceding species), inhabits the United States. (See Plate VIII., figures 4 and 2.) It lives well in captivity; and it even appears that a pair bred at Malmaison in 1809. This animal is frequently brought alive to Europe. Several other species inhabit the Eastern Islands.[4]

GENUS CHEIROMYS. Cuv. Geoff. Incisors $\frac{2}{2}$, canine $\frac{0-0}{0-0}$, molars $\frac{4-4}{3-3}$; $= 18$. Five toes to all the feet,—those of the anterior extremities very long and slender. The hind feet resemble hands, and are furnished with a short opposable thumb. Two inguinal mammæ.

---

[1] As in the dormice, Genus *Myoxis*.

[2] The fifth molar of the upper jaw seems to occur only in the young, and disappears in the adult state.

[3] See Desmarest's *Mammalogie*, p. 332, and the article *Ecureuil* of the *Diction. Class. d'Hist. Nat.* t. vi. p. 67.

[4] Horsfield's *Zoological Researches*, liv. 4 and 5.

This singular genus, regarding the true position of which in the system a great diversity of opinion exists among naturalists, contains only one species, the *aye-aye* of Madagascar or long-fingered Lemur of Shaw (*Lemur psylodactylus*, Schreber, *Sciurus Madagascariensis*, Gmelin). This animal is of the size of a hare, its colour brown mingled with yellow, its ears large and almost bare, its tail very long, and rather densely clothed with long blackish hair. (See Plate VIII., figures 3 and 6.) The aye-aye is slow in its movements, of timid disposition and nocturnal habits. It was discovered by Sonnerat on the eastern coast of Madagascar. Little is known of its natural history; but a pair, kept alive for some months by the French traveller, fed on boiled rice, in the eating of which they made use of their long fingers, pretty much in the way in which the Chinese employ their chop-sticks. In a state of freedom it is said to pick out larvæ and other insects from beneath the bark of trees. In its distinct orbits, the form of the hind feet, and other characters, it seems allied to the quadrumanous order (at the termination of which it is placed by M. Desmarest), but its teeth are those of the Rodential tribes.

GENUS ARCTOMYS, Gmel. *Mus*, Linn. Incisors $\frac{2}{2}$, canines $\frac{0-0}{0-0}$, molars $\frac{5-5}{5-5}$; $= 22$. Anterior paws with four fingers, and the rudiments of a thumb; posterior with five. Tail of medium length, or short.

The marmots are subterranean dwellers, living together gregariously, and subject to the torpid state in winter. Although they feed on roots and other vegetation, the somewhat pointed tubercles of the molar teeth indicate a departure from the strictly herbivorous character, and they are easily induced to eat both flesh and insects. They are usually extremely fat, prior to the assumption of the torpid state, and the epiploon is then furnished with numerous adipose leaflets; when they awake again on the return of spring, they are very thin, and their weight has become sensibly diminished, a proof that the fatty substance with which they are so amply furnished, supports the system not only in hybernation, but also during those trying periods when they are roused by any accidental alternation of temperature.[1] It is seldom, however, that they are exposed to sudden changes in those deep burrows, in which they take their winter sleep. The genus is at present composed of a great amount of species, the majority of which inhabit the temperate and colder regions of both continents. Above a dozen occur in North America, and (including the three species brought from Buckharia by M. Eversham), about eight are found in Europe.[2]

The most generally known species is the marmot of the Alps (*Arct. marmotta*, Gmel., *Mus alpinus*, Linn.), an animal somewhat larger than a rabbit, of a yellowish-grey colour, ashy towards the head, the upper part of which, and the end of the tail, are black. It inhabits high mountains immediately beneath the line of perpetual snow. Though of a stupid aspect, it is a creature not only of great instinctive intelligence, but also susceptible of education, while its habits, in a state of nature, are in every way worthy of attention. Several individuals combine in forming a subterranean retreat, contrived with great art, and consisting of an oval cavity or general receptacle, with a large canal or passage, divaricating so as to present a couple of outlets. These recesses are generally made on declivities, and are supplied during autumn with an ample store of moss and hay. During the joyous summer season the alpine marmots are often seen sporting near their holes, or sitting upright in the enjoyment of the genial sunshine; but it is said that a sentinel is usually placed on the summit of a neighbouring crag, to give warning of approaching danger. Certain it is that they are very wary, and not easily surprised at any distance from their subterranean retreats. When the increasing cold of autumn betokens the approach of their long continued winter sleep, they betake themselves to their chambers, which they have previously furnished with the sweet summer hay. With the same, or some similar material, they also close up the opening to their dwelling, and soon fall into a torpid state, which continues till the spring. When they first enter their winter quarters they are extremely fat, but become emaciated after the lapse of a few months. If carefully dug up they may be carried away without awakening; but the heat of a warm chamber speedily restores them to active life. In like manner, if well cared for in confinement, they do not assume the torpid state. From these, and other facts well known to naturalists, it would appear that hybernating animals are not condemned to torpidity by any inherent quality of their nature, but that it is rather a provisional faculty, dependent on external circumstances, and may consequently be interrupted, postponed, or altogether prevented, by regulating the conditions under which the individual is placed.[3] The Alpine marmot is less productive than most of its order. It brings forth only once a year, and produces four or five young at a birth. These increase rapidly, and are not only easy to tame, but may be taught to perform various tricks and gesticulations. In a domestic state they are almost omnivorous, and in eating they sit upright, and use their paws like a squirrel.

Another noted species is the *bobac* or Polish marmot (*Arctomys bobac*, Gmelin). It is found in Poland, in the basins of the Dnieper and Borysthenes, and spreads through the north of Asia into Kamtschatka. It lives in groups of from twenty to forty, digging deep excavations on the southern sides of hills of no great elevation, and resembles the preceding species in its general habits. The souslik or variegated marmot (*Arctomys citillus*, Gmel.) differs in not being gregarious. It is of a more irascible disposition, and exhibits a tendency to prey on animal food. In addition to the supply of hay, chiefly used for bedding by the other species, this kind stores up roots, nuts, grain, &c. from which its winter sleep may be inferred to be less profound. Pallas, indeed, informs us, that such as are occasionally found in granaries are observed in motion even during the winter season.[4] The so-called variegated or Siberian marmot has a widely extended distribution, occurring in Austria, Bohemia, and European Russia, and spreading northwards into Siberia, Kamtschatka, and the Aleutian islands, and southwards to Persia and Hindustan. The species of this genus are likewise numerous in North America;[5] of these, however, we shall here notice only the

---

[1] Mangili's *Mémoire sur le Lethargie des Marmottes.*

[2] For the species see Pallas's *Nov. sp. Quadrup. e Glir. Ord.* and the *Fauna Boreali-Americana*, part i.

[3] See the article ANIMAL KINGDOM of this work, vol. iii. p. 180.

[4] It may be here noted, however, that under the title of *Mus citillus*, Pallas is supposed to have described three distinct species of marmot, two of which he regarded as varieties of the other. The actual distribution of each is therefore probably more circumscribed. See *Novæ species Quadrupedum e Glirium Ordine*; and for the recent species, *Voyage à Boukhara*, par M. le Baron Meyendorff, in 1820, in which the animals collected by M. Eversman are described by Lichtenstein.

[5] For the Marmots of the New World, see Godman's *American Natural History*, vol. ii., Dr Harlan's *Fauna Americana*, the *Travels* of Lewis and Clarke, and Sir J. Richardson's work already so frequently referred to.

Quebec marmot (*Arctomys empetra*, see Plate VIII., figures 5 and 8) of Pennant.[1] It inhabits woody districts, at least as far north as lat. 61°. Although it is a subterranean species, it also climbs trees and bushes, probably in search of buds or other vegetation. The natives capture it by pouring water into the hole which it inhabits. They consider its flesh as a delicacy when in good condition. Its fur, however, is of no value.

GENUS MYOXIS, Gmelin, *Mus*, Linn. Incisives $\frac{2}{2}$, canines $\frac{0-0}{0-0}$, molars $\frac{4-4}{4-4}$; $= 20$. No cheek pouches. Anterior paws with four toes and a rudimentary thumb; posterior with five. Tail long, sometimes round and bushy, sometimes depressed and distichous, occasionally tufted only at the extremity. Hair very fine and soft. No cœcum.

The beautiful species, commonly called *dormice*, which constitute this genus, seem characteristic of Europe. They resemble squirrels in many of their habits, live in woods, and store up provisions for their winter store, although they pass most of that season in torpidity.[2] Their food consists chiefly of nuts and fruits, but they are said to attack occasionally the eggs and young of small birds. They pair in spring, and bring forth usually about five young in summer. Many curious observations have been made upon the nature of their hybernal sleep by Mangili, Saissy, Edwards, and others. Respiration is suspended and renewed at regular intervals, which vary, however, with the temperature. Thus, at 3° an individual observed by Mangili respired twenty-four or twenty-five times consecutively in a minute, after four minutes of repose. Their bodily temperature also falls. A lerot or garden dormouse, which in summer shewed a heat of 36° 5′, exhibited in December only 21°. Edwards has shewn that hybernating animals habitually produce less heat than other warm-blooded species, and that in that respect they continue permanently under the same conditions as the young of ordinary animals.

The fat dormouse (*Myoxis glis*, see Plate VIII., figure 7) is the most nearly allied to the squirrels. It dwells in forests, climbs trees, and leaps from branch to branch with considerable agility. It builds its bed in hollow trees, or in rocky clefts, dislikes moisture, and rarely descends to the ground. It is confined to the warmer and temperate parts of Europe, and was used by the Romans (as it still is in Italy) as food. That luxurious people fattened it for the table in receptacles called *Gliraria;* and Martial was of opinion, that in spite of long continued abstinence it became fattened by its winter sleep:

> "Tota mihi dormitur hiems; et pinguior illo
> Tempore sum quo me nil nisi somnus alit."

The flavour of its flesh resembles that of the guinea-pig. The lerot or garden dormouse (*M. nitela*) is more numerous and widely spread than the preceding. It inhabits temperate Europe as far north as Poland, and frequently occurs in gardens and outhouses. It inhabits holes in walls and hollow trees, and is injurious from its habit of climbing espalier trees, and eating the best and ripest fruit, especially peaches. It is itself uneatable. The muscardine (our English dormouse, *Myoxus muscardinus*, Gmelin, *Mus avellanarius*, Linn.) is scarcely larger than a common mouse. It never enters houses, but inhabits woods, where it makes a nest like that of the squirrel, composed of interlaced herbage opening from above, and usually placed on a hazel bush, or some low growing tree. It hybernates in hollow trees, occurs over Europe from Italy to Sweden, and is the only British species. Although extremely lethargic it is easily roused from torpidity, by either a diminution or increase of temperature. M. Mangili exposed a dormouse in a lethargic state to an artificial cold of 10°, and it died in twenty minutes. When opened a great quantity of blood was found in the ventricles of the heart and in the principal vessels connected with the lungs, while the lungs themselves, as well as the veins of the neck, head, and brain, were much distended.

GENUS ECHIMYS, Geoff. Incisives $\frac{2}{2}$, canines $\frac{0-0}{0-0}$, molars $\frac{4-4}{4-4}$; $= 20$. No cheek pouches. Four toes and the vestige of a thumb on the anterior feet; the posterior with five toes. Tail long, scaly, slightly haired. Fur coarse, and intermingled with flattened spines.

This genus consists of several South American species usually designated *spiny rats*, although in some the hair is of the usual kind. We know little of their history or habits. The red species (*Ech. spinosus*) is described by Azara as digging burrows in dry and sandy soils, four or five feet long, about eight inches beneath the surface, and sometimes so numerous and close together, as to render precaution necessary on the part of the pedestrian. It measures about eight inches in length.

GENUS HYDROMYS, Geoff. Incisives $\frac{2}{2}$, molars $\frac{2-2}{2-2}$; $= 12$. Feet with five toes, the thumb almost enveloped in the skin, the anterior toes free, those of the hinder extremities connected by a swimming membrane. Tail nearly as long as the body, cylindrical, pointed at the extremity, and covered with coarse hair.

Two Australasian animals (*H. leucogaster and chrysogaster*, Geoff.[3]), by some regarded as varieties of each other, constitute this obscurely known genus. The yellow-bellied species was described from a single individual killed by a sailor on an island in the straits of Entrecasteaux, while it was endeavouring to hide itself beneath a heap of stones. (See Plate VIII., figures 9 and 12.) Its fur is softer and finer than that of the white-bellied species. Both kinds measure about a foot in length, besides the tail, which extends eleven inches. In the first edition of the *Règne Animal*, they were erroneously regarded as natives of Guiana, and their supposed attributes are still commingled with those of a South American animal of amphibious habits, called the *Coypou* (genus *Myopotamus* of Commerson). Setting aside, then, the generalities which apply to the latter animal, we believe that nothing is known of the habits of the Hydromys. They are, in the mean time, inferred to resemble those of our water rats.[4]

We shall here merely name the

GENUS CAPROMYS of Desmarest, which contains two species native to the island of Cuba, where they are known to have been used as food by the natives. They resemble enormous rats.[5]

GENUS MUS, Cuv. Desm. Incisives $\frac{2}{2}$, molars $\frac{3-3}{3-3}$;

---

[1] *Arctic Zoology*, vol. i. p. 111. The Quebec marmot of Forster (*Phil. Trans.* lxii. p. 378), is, however, another species—the *Arctomys Parryi* of Richardson.

[2] The only exotic species with which we are acquainted (*M. Coupeii*, F. Cuvier, *M. murinus*, Desm., an animal imported from the Cape of Good Hope by Delalande), although probably in its native country active throughout the year, was found to become lethargic when exposed to the cold of Europe.

= 16. Anterior feet with four toes and a rudimentary thumb, the posterior with five. Tail long, naked, and scaly.

This genus, still of great extent, is now restricted to the rats and mice properly so called, an omnivorous race, some of which have followed man throughout his almost universal migrations. Wherever European nations have colonized, these small but adventurous creatures have accompanied the merchant or the mariner; and from the forlorn settlements of the fur traders of North America to the populous cities of Southern Asia, their sly and furtive habits are the source of equal annoyance.

The common brown rat of this country (*M. decumanus*) is believed to be an eastern animal, a native of Persia and Hindustan, which made its appearance in the western countries of Europe only during the earlier half of last century. It is a bolder and more powerful species than its predecessor the black rat, which it is said to have nearly extirpated.[1] It burrows under the foundations of walls and houses, makes its way into drains of foul water, swims with great facility, abounds in sea-port towns, and frequently establishes itself on board of ship. It is extremely prolific. This species is now well known in America and the colonies. It was unknown, even in the maritime towns of France, prior to 1750; and according to Pallas, was unobserved in Siberia and Russia before 1766. About that period they were seen to arrive in great troops towards the embouchure of the Wolga, and in the towns of Astracan and Jaitzkoi-Gorodok, appearing to come from the western desert, that is, from the European side.

The black rat (*Mus rattus*) is a smaller animal, of a darker colour, a more elongated head, and sharper muzzle than the preceding. It is equally omnivorous, but less productive. Its original country is extremely doubtful. Ancient authors make no mention of it, and the prevailing belief is that it made its way into Europe during the middle ages. It is still the prevailing species in some parts of the continent, but is now comparatively rare in Britain. Dr Fleming, however, observes, that "the period of their extirpation is far distant. They still infest the older houses of London and Edinburgh, and in many districts of the country they are common."[2] It was observed during the great fires which occurred in the ancient quarter of the last named city in the year 1824, that such rats as were dislodged from garrets and other lofty places, were all of the black kind.

Foreign countries produce various species of the rat tribe unknown to Europe. Of these we shall briefly describe the Malabar rat of Dr Shaw,—*Mus giganteus* of General Hardwicke,—a species of enormous size.[3] The nose is rounded, the under jaw much shorter than the upper, the cutting teeth broad, incurved, compressed. The body is thick, and greatly arched, the upper portion black, the under inclining to grey. The legs and toes are black, and the tail, thinly covered with hair, measures two and a half inches in circumference at the root. The specimen just noticed was a female, and weighed two pounds eleven ounces and a half. The male weighs above three pounds, and, including the tail, which is above a foot long, measures nearly thirty inches in length. This huge rat is found in many places on the Coromandel coast, in Mysore, and in several parts of Bengal, between Calcutta and Hurdwar. It is partial to dry situations, and scarcely ever occurs at a distance from human dwellings. According to General Hardwicke, the lowest caste of Hindoos eat the flesh of this rat in preference to that of any other species. It is extremely mischievous, and will burrow to a great depth, passing beneath the foundations of stores and granaries, unless these are very deeply laid; and it perforates with ease the walls of such buildings as are formed of mud or unburnt bricks. It is also destructive in gardens, from its habit of turning up the seeds of all kinds of leguminous plants. Fruits likewise suffer from its depredations, and it will even attack poultry when at all stinted in its vegetable diet. The bite of this species is considered dangerous; and a European serving in the Honourable Company's artillery is known to have died in the Doub of confirmed hydrophobia, in consequence of having been bit by it. One of the largest and most destructive rats with which we are acquainted is the *pilori*, or musk-rat of the Antilles (*M. pilorides*, Pallas and Gmelin), which measures fifteen inches in length, exclusive of the tail.[4]

Several foreign rats (not to be confounded, however, with the genus *Echimys*, already noticed) have a portion of their hair so strong and stiff as to be almost spiny. Such is the Perchal rat (*Mus Perchal*, Shaw), a species which measures above a foot in length, exclusive of the tail. It inhabits houses in the town and neighbourhood of Pondicherry, where it serves as food. Another spiny species occurs in Egypt, and is described by Geoffroy under the name of *Mus Cahirinus*.

Of the smaller species, or mice, we need scarcely describe the external aspect. The common domestic species (*Mus musculus*) was well known to ancient writers, and now occurs in most countries of the known world. It is amazingly prolific, sometimes producing seventeen at a birth. Aristotle's experiment in relation to this point has been often quoted. He placed a pregnant female in a vessel of grain, and after the lapse of a short period he examined his store, and found the grain greatly diminished, but the mice increased to 120. To the same genus belongs a somewhat larger species, called the long-tailed field mouse (*M. sylvaticus*), which resembles the preceding in the colour of its upper parts, but has the sides more rufous, the ears larger, the head longer, and the eyes more prominent. It dwells in fields, woods, and gardens, stores up seeds and roots in autumn, and is said to become torpid in very cold weather. This species is extremely abundant in certain seasons, and is often very destructive in plantations, by gnawing asunder the seedling trees or devouring the seeds. Buffon was of opinion that it did more damage in these respects than all other quadrupeds and birds together. They are killed abroad by fastening a roasted walnut to a stick, the latter supporting a large stone. In this manner above 2000 have been killed between the 15th November and the 8th of December, in a piece of ground not exceeding forty French arpents. The harvest mouse of White (*M. messorius*) is the smallest of British quadrupeds, the length of its body measuring only about two inches and a quarter. It builds its nest above ground. The one described by Mr White was composed of the blades of wheat, was perfectly round in its form, of the size of a cricket ball, with an aperture so ingeniously contrived, as to be discovered with difficulty. It contained eight young ones, all blind and naked, and was suspended in the head of a thistle. It is also often hung amid the blades of standing corn. The harvest-mouse, like most of the field species, is more frequently met with in the autumn than during any other season. It seeks protection from the winter's cold in hay or corn ricks, or in burrows beneath the earth. We have ourselves found it several times in the neighbourhood of Edinburgh. It does not appear to have been as yet generally recognised on the continent of Europe, though well known in some of the provinces of France, where of late a still smaller species has been discovered, the *mulot nain*, *M. pumilus* of F. Cuvier.

---

[1] We find the above observation recorded in all modern books of natural history,—Pennant's opinion having been followed by our English compilers; and the same sentiment prevails in most foreign works. "Il est vorace," says M. Desmarest, "fait la guerre la plus acharnée au rat noir," &c. *Mammalogie*, p. 299. Neverthless, we have sought in vain for the evidence on which such supposition has been founded. "On the contrary," says Dr Fleming, "I know that they have lived for years under the same roof, the brown rat chiefly residing in holes of the floor, the other chiefly in holes of the roof." *British Animals*, p. 20.

[2] Ibid.

[3] *Linn. Trans.* vol. vii. p. 306.

[4] *Règne Animal*, t. i. p. 201.

The American field-mouse (*Mus leucopus*, Rafinesque) inhabits the northern districts of the New World, and extends across the whole country from the shores of Hudson's Bay to the mouth of the Columbia. It becomes an inmate of the dwelling-houses as soon as any have been erected at a trading post. "The gait and prying actions of this little creature," says Sir J. Richardson, "when it ventures from its hole in the dusk of the evening, are so much like those of the English domestic mouse, that most of the European residents at Hudson's Bay have considered it to be the same animal, altogether overlooking the obvious differences of their tails and other peculiarities. The American field-mouse, however, has a habit of making hoards of grain or little pieces of fat, which I believe is unknown of the European domestic mouse; and what is most singular, these hoards are not formed in the animal's retreats, but generally in a shoe left at the bedside, the pocket of a coat, a nightcap, a bag hung against a wall, or some similar place."[1] This species may be regarded as the representative of the *Mus sylvaticus* of Europe. In the stoat or ermine it finds a most inveterate and deadly foe, being frequently pursued by that greedy bloodsucker even into the sleeping apartments of the settlers.

Genus Gerbillus, Desm. *Meriones*, Illig. Incisives $\frac{2}{2}$, molars $\frac{3-3}{3-3}$; $=16$. Anterior feet short, furnished with four toes, and a rudimentary thumb; the posterior long, with five toes. Tail long, and covered with hair.

The species of this genus are peculiar to the warmer portions of the ancient continent. They may be described as long-footed rats, allied in many respects to the gerboas, with which indeed they have been frequently confounded. As an example we may mention the *Mus tamaricinus* of Pallas, a subterranean animal, inhabiting the southern shores and deserts of the Caspian Sea. An Indian species (*G. Indicus*) was discovered by General Hardwicke;[2] and several others inhabit Africa, from Nubia to the Cape. They are great leapers.

Genus Meriones, F. Cuv. Separated from the preceding on account of the greater length of the hind legs, the nakedness of the tail, and the existence of a very small tooth in front of the molars of the upper jaw.

The species are American, and the best known is that called the jumping mouse of Canada, described as a gerboa by General Davies.[3] It is an animal of extreme agility, of the size of a mouse, with a very long tail. "The first I was so fortunate to catch," says the gentleman just named, "was taken in a large field near the falls of Montmorenci, and by its having strayed too far from the skirts of a wood, allowed myself, assisted by three other gentlemen, to surround it, and after an hour's hard chase to get it unhurt, though not before it was thoroughly fatigued, which might accelerate its death. During the time the animal remained in its usual vigour, its agility was incredible for so small a creature. It always took progressive leaps of from three to four, and sometimes of five yards, although seldom above twelve or fourteen inches from the surface of the grass; but I have frequently observed others in shrubby places, and in the woods, among plants, where they chiefly reside, leap considerably higher. When found in such places it is impossible to take them, from their wonderful agility, and their evading all pursuit, by bounding into the thickest part of the cover they can find." On the approach of cold weather it descends into the earth, and passes the winter in a state of torpidity. Another of these species has been described under the name of Labrador jumping mouse.[4] It is a very common animal in the fur countries as far north as Great Slave Lake, but Sir J. Richardson did not obtain any precise information regarding its habits.[5]

Genus Cricetus, Cuv. Teeth as in the genus *Mus*, but the tail is short, and clothed with hair, and the mouth is provided with cheek pouches, in which the species transport grain and other provisions into their subterranean chambers.

The most noted is the hamster (*Cricetus vulgaris*, Desm., *Mus cricetus*, Pallas; see Plate VIII., figure 10), an animal of variable colour, somewhat larger than a rat, of a thicker form, with a shorter tail. Although it occurs in Lower Alsace, it is rare in Europe to the west of the Rhine, but is widely spread from that river to the Danube on the south-west, and north-easterly through a vast extent of country into Siberia. It lives on roots, fruits, herbs, and other vegetable produce, and is said to be much attached to the grain of the liquorice plant. Some authors allege that it also preys occasionally on small birds, mice, &c. Though easily tamed, it is a fierce, resentful, pugnacious creature, and has been known to spring upon the muzzle of a horse, and hold on with its teeth till killed. When preparing for defence or attack, it empties its cheek pouches, and then so inflates them with air that its head and neck seem larger than the whole body. It then rises on its hind legs, and making a sudden spring, seizes on its adversary with the most obdurate tenacity. It will even spitefully grasp, and perseveringly maintain its hold of a piece of hot iron. Though the hamster occurs in great numbers, it is so far a solitary animal, that each inhabits a separate hole. It lays up during the summer season an ample and varied store, and is extremely injurious in many countries, from the quantity of grain which it conveys from time to time, in its cheek pouches, to its subterranean dwelling. These vary in depth and the number of their divarications with the age of the animal,—a young individual making them hardly a foot in depth, while the elders sink them four or five. The principal chamber is lined with hay, and serves as a sleeping room, while the other apartments contain the provisions.[6] These, it is said, will amount, for a single individual, to the weight of a hundred pounds. "On the approach of winter," says Dr Shaw, "the hamster retires into his subterraneous abode, the entry of which he shuts up with great care; and thus remaining in a state of tranquillity, feeds on his collected provision till the frost becomes severe; at which period he falls into a profound slumber, which soon grows into a confirmed torpidity, so that the animal continues rolled up, with all its limbs inflexible, its body perfectly cold, and without the least appearance of life. In this state it may be even opened, when the heart is seen contracting and dilating, but with a motion so slow as to be scarce perceptible, not exceeding fifteen pulsations in a minute, though in the waking state of the animal it beats a hundred and fifty pulsations in the same time. It is added, that the fat of the creature has the appearance of being coagulated, that its intestines do not exhibit the smallest symptoms of irritability on the application of the strongest stimulants, and the electric shock may be passed through it without effect. This lethargy of the hamster has been generally ascribed to the effect of cold alone; but late observations have proved, that unless at a certain depth below the surface, so as to be beyond the access of the external air, the animal does not fall into its state of torpidity, and that the severest cold on the surface does not affect it. On the contrary, when dug up out of its burrow, and exposed to the air, it infallibly awakes in a few hours. The waking of the hamster is a gradual operation: he first loses the rigidity of his limbs, then makes profound inspirations, at long intervals; after this he begins to move his limbs, opens his mouth, and utters a sort of unpleasant rattling sound. After continuing these operations for some time, he at length opens his eyes, and endeavours to rise, but reels about for some time, as if in a state of intoxication, till at length, after resting a small space, he perfectly recovers his usual powers. This transition from torpidity to activity requires more or less time, according to the temperature of the air, and other circumstances. When exposed to a cold air, he is sometimes two hours in waking; but in a warmer air the change is effected in half the time."[1]

[6] In the history of the hamster, as in that of other foreign species, the habits of which we have no means of ascertaining from personal observation, we are necessarily dependent for our information on the published works of authors of repute. We are sometimes, however, rather at a loss by which statement to be led, where there is a contrariety of evidence; as, for example, in regard to the species in question. "Il est *commun*," says Cuvier, "dans toutes les *contrées sablonneuses* qui s'etendent depuis le nord d'Allemagne, jusqu'en Siberie" (*Règne Animal*, t. i. p. 205); "Il *evite*," observes M. Desmoulins, "les *terrains sablonneux*, et ceux qui sont trop arrosés" (*Diction. Classique d'Hist. Nat.* t. viii. p. 34.). So in like manner regarding the entrances to their subterranean stores, there is a disparity of opinion. "Les cavités," according to M. Desmarest, "où elles (diverses semences, &c.) sont situées à deux pieds et demi ou trois pieds sous terre, et elles communiquent au dehors par deux galeries, dont *une, oblique, est le chemin d'usage ordinaire*, et l'autre, perpendiculaire, ne sert que dans les cas d'alerte" (*Mammalogie*, p. 310); while Dr Shaw observes, that "each hole has two apertures, the one descending obliquely, and *the other in a perpendicular direction*, and it is through this latter that the animal *goes in and out*" (*General Zoology*, vol. ii. p. 97.). We adduce these discrepancies to shew the difficulties which sometimes beset even the humble labours of a conscientious compiler. How almost insuperable they become in the way of original observation, may be inferred from the few precise additions to actual knowledge which we find amid the multiplied channels of modern information.

Numerous other species of this genus are described by naturalists, and the beautiful little South American animal called *chinchilla* (*C. laniger*, Geoff. and Desm.), so remarkable for the softness of its fur, has been usually classed with the hamsters.[2] New genera have been formed by M. Rafinesque Smaltz, and some other writers, for the reception of several of the reputed hamsters of North America, such as the sand rat, camas rat, pouched rat of Canada, &c.; but into the history of these we cannot enter.[3]

Genus Fiber, Cuv., Desm. Incisives $\frac{2}{2}$, molars $\frac{3-3}{3-3}$; $= 16$. Hind feet with a marginal row of long hairs, but not webbed.[4] Tail long, laterally compressed, scaly or granular, and thinly haired.

Of this genus the only species as yet distinctly characterized is *Fiber zibethecus*, or musk rat of Canada, commonly called the *musquash*. It is an animal of amphibious habits, measuring above a foot in length, with a thick flattish body, a short head, indistinct neck, thighs hid in the body, very short legs, and large hind feet. The fur greatly resembles that of the beaver, but is shorter, with the down coarser and of less value. Although it resists the water when alive, it is easily wetted after death. The musquash is peculiar to North America, where it extends from about north latitude 30°, almost to the mouth of the Mackenzie River in latitude 69°. They feed, for the most part, on vegetable substances (in summer they are said to devour the fresh water mussels), and their favourite abodes are small grassy lakes or swamps, or the grassy borders of slow-flowing streams which possess a muddy bottom. They are very prolific, bringing forth sometimes three broods in a season, but their numbers are often checked by a great mortality which attacks them at uncertain intervals, from some unknown cause. The districts in which they abound are also subject to frequent inundations, which, covering all the lower grounds, occasion the death of many by drowning, and in severe winters they are almost extirpated from certain districts by their swampy dwellings being frozen over. In such cases, Sir J. Richardson informs us, they are driven by famine to devour each other. In a state of nature they are rather watchful than shy, that is, they will approach close to a canoe, but will dive the instant they perceive the flash of a gun. According to Hearne they are easily tamed. Their fur is extensively used in the fabrication of hats,—between four and five hundred thousand skins being annually imported to Great Britain. The Indian hunters spear these animals through the walls of their mud houses.

Genus Arvicola, Cuv. Incisives $\frac{2}{2}$, molars $\frac{3-3}{3-3}$; $= 16$. Hind feet neither palmated nor ciliated. Tail round, haired.

This genus contains, among many other species, two small British quadrupeds,—the water rat (*A. aquatica*) and the short-tailed field mouse (*A. agrestis*). The former inhabits holes by the banks of lakes and rivers. In this country, its disposition, so far as yet observed, is herbivorous, but French and Italian naturalists state that it preys also on insects, reptiles, and the spawn of fishes. The latter is very common in fields, gardens, and the outskirts of woods, in all of which it sometimes occasions no small damage. Although M. Desmarest assigns "l'ancien continent" as the geographical range of the genus Arvicola, yet several species inhabit North America. Indeed the French author has himself described *A. xanthognathus* as native to the shores of Hudson's Bay. Of the species of Northern Asia, one of the most singular is the economic rat (*A. economus*, Desm.), so called from the great skill and sagacity which it displays in providing the supplies of winter. This labour rests chiefly with the female,—the male during summer leading a solitary life, dwelling in old deserted holes, and feeding on berries and other produce of the season. When cold weather approaches, both sexes wisely betake themselves to the same hole. The occasional migrations of this species are scarcely less remarkable than those of the lemming. The cause of these movements is quite unknown, although Pallas imagines (and every one is entitled to indulge that poetical and pleasing attribute) that they are occasioned, at least in Kamtschatka, by some uneasy sensation produced by the subterranean fire of that volcanic region. M. Bosc conceived that he had found this species in the forest of Montmorency, and we have also been informed of its supposed occurrence in Switzerland. Although those localities are somewhat doubtful, we must at the same time bear in mind, that several of the species are very extensively distributed,—*Arvicola pennsylvanicus* of Ord (commonly called Wilson's meadow-mouse) being by some regarded as identical with our *A. agrestis*.

Genus Georychus, Illig. *Lemmus*, Desm. Scarcely differs from the preceding, except in the shortness of the ears and tail, and the larger and stronger claws, more fit for digging.

We here place the celebrated lemming (*Mus lemmus*, Linn., *Lem. Norvegicus*, Desm.), of the migratory movements of which we have such singular records. It is a northern animal, an inhabitant of the mountains of Norway and Lapland, of the size of a rat, and clothed with fur varied by black and tawny. The specimens from different localities do not altogether accord either in size or colour. The lemming differs from many of its congeners, and indeed from several species of its own genus, in having five well developed toes to the anterior feet, instead of four toes and a rudimentary thumb. We have heard less of late of this animal than might have been anticipated from the extraordinary accounts which the preceding century furnished of its history. The lemmings were described as natives of the mountains of Kolen, in Lapland, and were said to appear once or twice in a quarter of a century " in numbers numberless," advancing in a straight line, unchecked by hill or dale, by lake or river, and devouring in their onward journey " every green thing." Even the anxieties of maternity do not slacken their march, for they have been known to produce their offspring while journeying, and to proceed as if nothing had happened, with a young one between their teeth, and another on their back.[1] Innumerable bands were seen to march from the Kolen, through Nordland and Finmark, to the Western Ocean, which, nothing daunted, they immediately entered, and after swimming about for some time, as might be expected, perished. Other bands were observed to take their route through Swedish Lapland to the Bothnian Gulf, where they were drowned in the same manner. When opposed by the peasants, they stood still and barked at them; and they themselves were not only barked at in return, but were swallowed in great quantities by the lean and hungry dogs of Lapland. The advent of these vermin is regarded as the omen of a bad harvest. They are followed in their journeys by bears, wolves, and foxes, which prey upon them incessantly, and regard them as the most delicious food.[2] These excursions seem to augur a rigorous winter, of which the lemmings in some way appear forewarned. For example, the season of 1742, remarkable for its severity throughout the circle of Umea, was comparatively mild in that of Lula, although situate further to the north; the lemmings migrated from the former, but remained stationary in the latter district. Whatever may be the motive of these journeys, they are certainly executed with surprising perseverance, and with the universal accord of the whole nation,—the *officina murium* pouring forth its entire hordes, and leaving scarce a remnant in their ancient habitation. The greater proportion perish before they reach the sea, and of course few survive to return to their ancestral homes. They do, however, endeavour to return; for the object of their travel to a far country, whatever it may be, is not to found a multiplied or more extended empire. This indeed is evident from the comparatively local restriction of the species; for the true lemming of the Scandinavian Alps does not appear to occur even in Russian Lapland; and the kind which inhabits the countries in the vicinity of the White and Polar Seas, as far as the mouths of the Obi, is a species or strongly marked variety, smaller by at least one-third, and of a different aspect and colour.[3] Their migratory propensities are, however, entirely the same in different countries; for the species which dwells among the northern extremities of the Ural Mountains, emigrates sometimes towards Petzora, at other times towards the banks of the Obi, and is followed, as usual, by troops of carnivorous and insatiate foes.[4] The domestic manners of the species are said to present this discrepancy, that the Norwegian lemmings lay up no provisions, and have only a single chamber in their subterranean dwelling-places, whereas the lesser kind excavate numerous apartments, and are provident of the winter season, by storing up ample magazines of that species of rein-deer moss called Lichen rangiferinus.[5]

[2] The chinchilla is now regarded as generically distinct. We shall notice it at the conclusion of our present order.

[3] See *Fauna Boreali-Americana*, part i., and Lesson's *Manuel de Mammalogie*.

[4] "Pieds de derrière demi palmés." Cuvier. "There is no vestige of a web." Richardson.

Many other lemmings occur in Siberia and the Tartarian deserts, and several in North America. Of the latter we may mention that from Hudson's Bay, *G. Hudsonius*, one of the most northern of known quadrupeds. It does not appear to have been met with as yet in the interior of America, but inhabits Labrador, Hudson's Straits, the coast from Church-hill to the extremity of Melville Peninsula, and the desolate islands of the Polar Sea. Its manners are imperfectly known, but Hearne states that it is so easily tamed, that if taken even when full grown, it will in a day or two become reconciled to captivity, and will voluntarily creep into its master's bosom. This species has no external ears, and scarcely any tail. " Les deux doigts du milieu," says Cuvier, " aux pieds de devant du male, ont l'air d'avoir les ongles doubles parceque la peau du bout du doigt est calleuse, et fait une saillie sous la pointe de l'ongle,—conformation qui ne s'est encore rencontrée que dans cet animal."[6] Sir J. Richardson, however, informs us, that the lower layer of the claw appeared to him to be not an enlargement of the callus, but rather of the same substance as the superior portion or nail proper.

GENUS DIPUS, Gmel. Incisors $\frac{2}{2}$, molars $\frac{3-3}{3-3}$, or $\frac{3-3}{4-4}$; $= 16$ or 18. Head broad. Eyes large. Ears long and pointed. Anterior feet with four toes, and a nailed wart in place of thumb. The posterior extremities of great length, and terminated by three or five toes. Tail very long, cylindrical, covered throughout with short hair, and terminated by a tuft.

The jerboas, called two-footed rats by ancient writers, are nocturnal animals, of subterranean habits, native to the central countries of the Old World. They feed on fruits and roots. One of their most remarkable characters consists in this, that the three middle toes are all supported by a single metatarsal bone, which thus resembles the canon bone of the ruminating tribes, an osteological feature unique, we believe, in the rodential order. Such of the species as have only three toes, have but a single metatarsal bone to the whole. The *Dipus jerboa (Mus sagitta*, Pall.) is abundant in Barbary, in Upper and Lower Egypt, and Syria, and makes its appearance again in more northern countries between the Tanais and the Volga. It feeds chiefly on bulbous plants, and is remarkable for the extreme celerity of its course, which it effects by a series of long and rapid bounds. Though its tail, from the cruel experiments of M. Lepechin, appears to be of great use in locomotion, it is not by any means thick and muscular like that of the kangaroo. The jerboa usually walks on all fours, but when alarmed it seeks its safety by prodigious leaps, executed with great force and rapidity. When about to spring, it raises its body by means of the hinder extremities, and supports itself at the same time upon its tail, while the fore feet are so closely pressed to the breast, as to be scarcely visible. Hence, probably, its ancient name of dipus, or two-footed. It then leaps into the air, and alights upon its four feet, but instantaneously erecting itself, it makes another spring, and so on in such rapid succession, as to appear as if rather flying than running. The experiments above alluded to consisted in maiming or cutting off the tails of these poor creatures. In proportion as that organ was reduced in length, their power of leaping diminished; and, when it was entirely lopped away, they not only could not run at all, but fell backwards whenever they attempted to raise themselves with a view to their accustomed spring. "The jerboa," says Bruce, "is a small harmless animal of the desert, nearly the size of a common rat, the skin very smooth, and the ends of the hairs tipt with black. It lives in the smoothest plains or places of the desert, especially where the soil is fixed gravel, for in that chiefly it burrows, dividing its hole below into many mansions. It seems to be apprehensive of the falling in of the ground; it therefore generally digs its hole under the root of some spurge, thyme, or absynthium, upon whose root it seems to depend for its roof not falling in and burying it in the ruins of its subterranean habitation. It seems to delight most in those places that are haunted by the cerastis, or horned viper. Nature has certainly imposed this dangerous neighbourhood upon the one for the good and advantage of the other, and that of mankind in general. Of the many trials I made, I never found a jerboa in the body of a viper, excepting one in that of a female big with young, and the jerboa itself was then nearly consumed."[1] This species is used as food, and its flesh, in taste, is scarcely distinguishable from that of a young rabbit. It is described at a remote period by ancient authors, and is represented in some of the earliest medals of the Cyrenaicum, sitting beneath an umbellated plant (supposed the *Silphium*), the figure of which is likewise preserved on the silver medals of Cyrene. The *Dipus jaculus* inhabits the Tartarian deserts, and other species occur in different regions, from the shores of the Caspian Sea to the banks of the rivers of Siberia. We here figure an African species, the *Dipus hirtipes* of Lichtenstein. (See Pl. VIII., figure 11.)

The largest species of the genus, as formerly constructed, is the Cape jerboa, *Dipus caffer*, Gmel. It differs from the others in having four molar teeth on each side of both jaws, five toes to the anterior feet, and only four to the posterior, the latter armed with broad claws almost resembling hoofs. It measures about a foot in length, exclusive of the tail, which extends fifteen inches. This species is remarkable for its great strength and activity, which enable it to spring from twenty to thirty feet at a single bound. It dwells in deep burrows in the mountainous regions to the north of the Cape of Good Hope, and is known to the Dutch colonists under the name of *springen haas*, or jumping hare. In consequence of the peculiarities of structure just referred to, it has been formed by Illiger into a separate genus, under the name of PEDETES (*Helamys*, F. Cuvier). (See Plate IX., figure 1.)

GENUS SPALANX, Guldenstaedt. *Aspalax*, Olivier, Desm. Teeth as in the rats and hamsters, but the incisives more projecting and exposed. Legs very short; all the feet furnished with five toes, with flat thin nails. External ears and tail scarcely perceptible.

The singular animal (*Mus typhlus* of Pallas) which forms the type of this genus, resembles the mole in its habits,—throwing up the earth from its burrows in the same manner, though furnished with much less powerful limbs. It measures nearly ten inches long, has a thick cylindrical body, a large triangular head, and no apparent eyes. Beneath the skin, however, there are small black points resembling eyes, although their functions, as organs of vision, are difficult to understand, in as far as they are covered over by skin and hair. "Whether the spalax be absolutely blind, or whether it receives any perception of light through the medium of the eye as an organ, does not sufficiently appear by what has hitherto been said by its describers. The presence of what may be called the vestige of an organ, seems perfectly consistent with other instances in which the application of such imperfect organ is not at all to be traced. On the contrary, it accords with that apparent unwillingness in nature to depart from prescribed laws. The total absence of an accustomed organ is much more anomalous in nature than the complete inutility of an imperfect one."[2] It has been generally assumed that the Greeks described our common mole *as blind*, under the name of ασπαλαξ. and modern authors, knowing that the sleek inhabitant of our pastures is possessed of eyes, though small ones, have prided themselves on their supposed correction of an ancient error; but the observations of Olivier go to prove that the mole of the Greeks was not the species of western Europe, but the animal in question, which spreads through Asia Minor into Persia and the south of Russia, between the Tanais and the Wolga. The original error probably lay with the Latin writers, who translated the word ασπαλαξ into talpa, and then applied the term to the mole of Europe. We may add, however, that Professor Savi of Pisa is of opinion that the aspalax is to be regarded as identical with the species of mole (*Talpa cæca*) which he discovered in the Apennines,[3] and which Baron Cuvier says is "tout à fait aveugle,"[4] by which we presume he merely means that its eyes are covered by the skin. M. Charles Lucien Bonaparte likewise regards these species as synonymous.[5]

We may here briefly notice the genus BATHIERGUS of Illiger, which, with several attributes of the preceding genus, is distinguished by four molars on each side both above and below, by a small though perceptible eye, and a short tail. The sand mole (*B. maritimus*, Plate IX., figure 2), as the larger species is usually called, is an animal of the size of a rabbit, which occurs abundantly along the sandy shores of the Cape of Good Hope, where it sometimes excavates the ground in such a manner as to produce inconvenience, if not danger, to horsemen. Another species, called the Cape rat (*B. capensis*), is destructive in gardens and pleasure grounds. A third has been described under the title of *B. hottentotus*, by MM. Lesson and Garnot.[6]

For the genera GEOMYS and DIPLOSTOMA of M. Rafinesque, and a few other groups of the Rodential Order, the characters of which we cannot here detail, we must refer the reader to the works quoted below.[7]

GENUS CASTOR, Linn. Incisives $\frac{2}{2}$, molars $\frac{4-4}{4-4}$; $= 20$. Eyes small. Ears short and rounded. Five toes to each foot, those of the hinder extremities united by a web or membrane. Tail broad, depressed, ovular, naked, and scaly. Two pouches (in the male) on each side of the genitals, containing an unctuous matter called castoreum.

As the description of the beaver, which alone constitutes our present genus, is recorded in almost every book of natural history, we shall here confine ourselves to a few particulars regarding its general habits, and as its history, as given by the traveller Hearne, has been characterized by competent authority as the most accurate which has been yet presented to the public, we shall here abridge it for the benefit of the same. We may, however, premise by observing, that naturalists have not yet been able to establish any distinctive characters between the gregarious beavers of North America, and the few that still survive in isolated pairs along the banks of a few great European rivers, such as the Rhone, the Rhine, and the Danube.[1] Those of Europe seem of somewhat larger dimensions, and of a paler coloured fur. (See Plate IX., figure 3.)

[7] Desmarest's *Mammalogie*, and Richardson's *Fauna Boreali-Americana.*

The situation of the beaver houses in America is found to be various. Where the animals are numerous, they inhabit lakes, ponds, and rivers, as well as those narrow creeks which connect the lakes together. They generally, however, prefer flowing waters, probably on account of the advantages afforded by the *current* for transporting the materials of their dwellings. They also prefer deepish water, no doubt because it yields a better protection from the frost. But it is when they build in small creeks or rivers, the waters of which are liable to dry or be drained off, that they manifest that beautiful instinct with which Providence has gifted them,—the formation of dams. These differ in shape according to the nature of particular localities. Where the water has little motion the dam is almost straight; where the current is considerable it is curved, with its convexity towards the stream. The materials made use of are drift wood, green willows, birch, and poplars; also mud and stones intermixed in such a manner as must evidently contribute to the strength of the dam; but there is no particular method observed, except that the work is carried on with a regular sweep, and that all the parts are made of equal strength. "In places," says Hearne, "which have been long frequented by beavers undisturbed, their dams, by frequent repairing, become a solid bank, capable of resisting a great force both of ice and water; and as the willow, poplar, and birch generally take root and shoot up, they by degrees form a kind of regular planted hedge, which I have seen in some places so tall, that birds have built their nests among the branches."[2] Their houses are formed of the same materials as the dams, with little order or regularity of structure, and seldom contain more than four old, and six or eight young beavers. It not unfrequently happens that some of the larger houses have one or more partitions, but these are only posts of the main building left by the sagacity of the beaver to support the roof, for the apartments, as some are pleased to call them, have usually no communication with each other except by water. Those travellers who assert that the beavers have two doors to their dwellings, one on the land side, and the other next the water, manifest, according to Hearne, even a greater ignorance of their habits than do those who assign to them an elegant suite of apartments, for such a construction would render their houses of little use either as a protection from their enemies, or as a covering from the winter's cold. Neither is it true that these animals drive stakes into the ground when building; they lay the pieces crosswise and horizontal. It is equally inaccurate to state that the wood work is first finished, and then plastered, for both houses and dams consist from the foundation of a mingled mass of mud and wood, mixed with stones, when such can be obtained. They carry the mud and stones with their fore-paws, and the timber between their teeth. They always work in the night, and with great expedition. They cover their houses late every autumn with fresh mud, which freezing when the frost sets in, becomes almost as hard as stone; and thus neither wolves nor wolverines can disturb their well-earned repose. When walking over their work, and especially when about to plunge into the water, they sometimes give a peculiar flap with their broad heavy tails; but they do not use these parts exactly as a mason uses his trowel, for a tame beaver will flap by the fireside, where there is nothing but dust and ashes.

The favourite food of beavers is the plant called *Nuphar luteum*, which bears a resemblance to a cabbage stalk, and grows at the bottom of lakes and rivers. They also gnaw the bark of birch, poplar, and willow trees. But during the bright summer days which clothe even the far northern regions with a luxuriant vegetation (the more beautiful as contrasted with the rigorous and long enduring winter) a more varied herbage, with the addition of berries, is consumed. When the ice breaks up in spring they always leave their embankments, and rove about until a little before the fall of the leaf, when they return again to their old habitations, and lay in their winter stock of wood. They seldom begin to repair the houses till the frost sets in, and never finish the outer coating till the cold becomes pretty severe. When they erect a new habitation, *they fell the wood early in summer*, but seldom begin building till towards the latter end of August. Some tame beavers kept by Hearne became extremely attached to human society, and were also remarkably fond of rice and plum-pudding. They would even eat freely of partridges and fresh venison. Kalm mentions a tame beaver which belonged to a gentleman of New York, and was in the habit of going about the house like a dog. A cat which inhabited the same dwelling, on producing kittens took possession of the beaver's bed without any opposition being offered; and ere long, when the cat went out, the beaver used to take a kitten between his paws, and hold it to his breast, as if to keep it warm, till the return of the proper parent.[3]

Dr Richardson informs us that the flesh of these animals is much prized by the Indians and Canadian voyagers, especially when roasted in the skin, after the hair has been singed off. This of course makes it an expensive luxury, the enjoyment of which it requires all the influence of the fur traders to restrain. Beavers are said to pair in February, to carry their young about ten weeks, and to bring forth from four to eight cubs by the middle or end of May. In regard to the geographical distribution of these highly interesting creatures, Pennant fixes their southern range in Louisiana, about latitude 30°, not far from the Gulf of Mexico, while Mr Say assigns as their limit the confluence of the Ohio and Mississippi, about seven degrees farther north. In the higher latitudes, their extension seems restricted by the absence or deficiency of wood, the districts called the Barren Grounds not yielding enough even of willows for their subsistence. Many are known to occur as high as latitude 68°, on the banks of the Mackenzie, the largest and best wooded of the American rivers that discharge themselves into the icy basin of the Polar Sea. The Iroquois are the greatest beaver catchers in Canada. There is no doubt that great injury has resulted from the indiscriminate capture of old and young, and the too frequent *trenching* of the same dams,—evils which the Hudson's Bay Company are at last endeavouring to remedy by the adoption of more prudent measures. "In the year 1743, the imports of beaver skins into the ports of London and Rochelle, amounted to upwards of 150,000; and there is reason to suppose that a considerable additional quantity was at that period introduced illicitly into Great Britain. In 1827, the importation of beaver skins into London, from more than four times the extent of fur country than that which was occupied in 1743, did not much exceed 50,000."[4]

There is an amphibious animal called the Coipu (*Mus coipus*, Molina), which dwells by the rivers of South America, and is allied to the beaver in many of its characters, except that its tail is narrow and elongated. Its fur, much used in the manufacture of hats, is known to merchants under the name of *racoonda*, and is imported in great quantities to Europe. This animal inhabits Chili, is very abundant in the provinces of Buenos Ayres and Tucuman, but rare in Paraguay. It is described by Desmarest as a hydromys (*H. coypus*[1]), and is mentioned by Azara under the name of *Quouiya*.[2] It is now regarded as forming a distinct genus under the title of MYOPOTAMUS, as first proposed, we believe, by M. Commerson.

DIVISION II. Clavicles incomplete or nonexistent.

GENUS HYSTRIX, Linn. Incisives $\frac{2}{2}$, molars $\frac{4-4}{4-4}$; = 20. Muzzle broad and blunt. Ears short and rounded. Tongue beset with prickly scales. Anterior feet with four toes and a rudimentary thumb, the posterior with five, the whole armed (except the small anterior thumb) with strong claws. Body protected by strong sharp-pointed spines of different length, intermingled with the hairs.

This genus is composed of four or five animals of very extraordinary aspect, known under the name of porcupines. They occur in Europe, Asia, Africa, and America, and have recently been formed into several minor generic groups, of which we shall give a brief sketch. All the species feed on fruits, roots, and grain, and either dig themselves subterranean dwellings, or seek retirement in the secure hollows of ancient trees.

The restricted genus HYSTRIX, Cuv., characterized by the dilatation of the muzzle and nasal bones, contains the European porcupine (*H. cristata*, Linn.), an animal which occurs in the south of Italy, Spain, Sicily, and Barbary. (See Plate IX., figure 4.) Indeed, the identical species, or one closely allied, extends to the Cape of Good Hope, and spreads from Persia into Hindustan. It measures above two feet in length. Its quills are very long, ringed with brownish-black and white. There is a kind of crest or mane of long bristles on the head and nape. The tail is short, and furnished with truncated hollow quills, suspended by a narrow pedicle, so that they rattle when the creature walks, like a half-filled quiver. Mr Brydone mentions that the porcupine is frequent in Sicily, in the district of Baiæ, and that he killed several during a shooting excursion in the Monte Barbaro. He dined upon his game, but found it luscious, and soon palling upon the appetite.[3] The singular aspect of this animal seems to have attracted the attention of the lovers of natural history at a very early period, and many fabulous attributes were added to the character of a creature in itself sufficiently curious. It was said to possess the power of darting its quills at pleasure with great force, and to a considerable distance, against its enemies; and Claudian observes, that it is itself at once the quiver, the arrow, and the bow:

> "Ecce, brevis propriis munitur bestia telis,
> Externam nec quærit opem, fert omnia secum
> Se pharetrâ, sese jaculo, sese utitur arcu!"

We may add, that Agricola states the Italian porcupine to be not indigenous to the south of Europe, but imported from India or Africa.

In the genus ATHERURA, Cuv., the head and muzzle are not dilated, and the tail is long, though not prehensile. It contains the *Hystrix fasciculata*, Linn., *Mus fasciculatus*, Desm., a native of India and the peninsula of Malacca.

The genus ERETISON, F. Cuvier, of which the cranium is flat, and the muzzle not dilated, the tail of medium length, and the quills short and half concealed by long hair, contains the well-known Canada porcupine (*H. dorsata*, Linn.). This species is distributed over a considerable extent of North America, from the 37° to the 67°. According to Dr Harlan, it makes its dwelling-place beneath the roots of hollow trees. It dislikes water, is cleanly in its habits, sleeps much, and feeds chiefly on the bark and leaves of *Pinus canadensis* and *Tilia glabra*. It is also fond of sweet apples and Indian corn. In the fur countries it is most numerous in sandy districts, covered with *Pinus Banksiana*, on the bark of which it delights to feed. Its spines are detachable by the slightest touch (some say by an act of volition on the part of the animal), and not unfrequently occasion the death both of dogs and wolves. Its flesh tastes like flabby pork, and, though relished by the Indians, is nauseous to the palate of a European.

The genus SYNETHERES of F. Cuvier (*Couendu*, Lacepede), contains certain South American species with prehensile tails, such as *H. prehensilis*, Linn., and *H. insidiosa*, Lichtenstein. (See Plate IX., figure 5.) The feet have only four claws, armed with nails, and they differ from the preceding species in their habit of climbing trees. Other generic groups have been proposed in relation to the genus Hystrix, but without having met with general reception on the part of naturalists.[4]

GENUS LEPUS, Linn. Incisives $\frac{4}{2}$, molars $\frac{6-6}{5-5}$; = 28. Anterior feet with five toes, posterior with four. Tail short. Cœcum very large, pouched, and divided by a spiral valve.

The species of this genus, familiarly known under the name of hares and rabbits, are spread over almost all the regions of the earth, from the tropical regions of Africa and America, to the islands of the Polar Sea. Their most distinctive character consists in their upper incisives being double, that is, each has a smaller one behind it. The soles of the feet, and the inside of the mouth (a character remarked by Aristotle), are covered with hair. The genus is not only one of considerable extent, but extremely natural,—the species of which it is composed corresponding both to the principal characters, and also to several others which are secondary and unessential, such as the colour of the fur, which is usually of a reddish-grey, with the eye placed in a spot of paler hue. The abdomen and under side of the tail seem almost always white, and the tips of the ears black. They are all of a timid disposition, extremely swift in their movements, and valuable to the human race, not more on account of the value of their furs, than of their nutritive and pleasant flavoured flesh. Several of the species resemble each other so closely as to be with difficulty distinguished.

The common hare (*Lepus timidus*) is known all over Europe, and a great part of Russia, Asia Minor, Syria, &c. The varying hare (*Lepus variabilis*) is somewhat larger in the body, with rather shorter ears and tail, its fur in summer being of a bluish-grey, and changing to white in winter. This remarkable alteration is said to take place in the following manner:—About the middle of September the grey feet become whitish, and before the end of the month all the four feet are white, and the ears and muzzle of a brighter aspect. The white colour gradually ascends the legs and thighs, and beneath the grey hair whitish spots may be observed, which continue to increase till the end of October; but still the back continues grey, while the eye-brows and ears are nearly white. From this period the change is rapid, and by the middle of November the whole fur is white, excepting the tips of the ears, of which the black is permanent. The back becomes white within eight days, and during the whole of this singular mutation no hair is shed. Hence it appears that the fur itself, though altered in aspect, remains unchanged. It continues white till the month of March, or later, according to the season, after which it again becomes grey. But the spring change differs in this respect from that of the early winter, that the hair is then completely shed.[1] This animal inhabits the alpine parts of Europe, but does not extend to the extreme north, as supposed by Pennant, the species of that locality being now distinguished by the name of Polar hare, *Lepus glacialis*, Leach. The size of the latter is equal to that of the largest English hare. It does not burrow, but seeks shelter among large stones and the crevices of rocks. Its flesh is more juicy than that of our own alpine or varying hare. The polar species is common in North America, but does not seem to advance southwards beyond the 58th parallel, and does not occur in wooded countries, though often seen in the vicinity of thin clumps of spruce fir. It extends to Melville Island. Several other species occur in America. The American hare, commonly so called (*Lepus Americanus*), bears a great resemblance to a rabbit, and seldom weighs more than four pounds. It is common in all the woody districts, and 25,000 have been taken at a single trading post in one season. They are imported into Britain under the name of rabbit-skins. The prairie hare (*Lepus Virginianus*) is a much larger animal, weighing from seven to eleven pounds. It can leap above twenty feet at a single bound. We cannot here allude to the species of southern latitudes.[2]

[3] *Tour in Sicily.*

[4] See *Memoires du Museum*, t. ix. p. 413.

The rabbit (*Lepus cuniculus*), now so common throughout the temperate and southern parts of Europe, is supposed to have been of African origin, and first imported into Spain. It differs greatly from the hare in its gregarious habits, its subterranean life, the whiter colour of its flesh, and less perfect state of the young when first produced. It is also much more prolific.[3]

A few species of the old genus Lepus, of which the ears are shorter, the limbs of more equal length, the clavicles almost perfect, and the tail wanting, form the generic group now called LAGOMYS. We shall here mention as an example the *Pika* of Northern Asia (*Lag. alpinus*, Plate IX., figure 6). It is about the size of a guinea pig, and inhabits the tops of high mountains, such as those of the Altaic range, and the cold heights of Siberia. It dwells in burrows, the clefts of rocks, and even (when it can get them) in the trunks of trees, and is sometimes gregarious, sometimes solitary. Towards the middle of August it collects and prepares a great mass of hay and other herbage for winter use, and in this labour several join together. These heaps sometimes measure more than eight feet in diameter, and equal or exceed the height of a tall man. This admirable instinct has rendered these little animals celebrated throughout the countries they inhabit. Their precious stores, however, are often discovered by the Siberian hunters of the sable, who convert them from their intended uses into fodder for their hungry horses.

In immediate succession to the porcupines, hares, and pikas, Baron Cuvier places those groups of the Rodential Order, which Linnæus and Pallas combined under the generic name of CAVIA, and of which the well known guinea-pig affords a familiar example. They are all natives of the New World, and, except in the imperfect condition of their clavicles, offer such disparity of structure as have induced, in comparatively recent times, the formation of the following genera.

GENUS HYDROCHÆRUS, Erxleben. Incisives $\frac{2}{2}$, molars $\frac{4-4}{4-4}$; = 20. Muzzle deep and blunt. Ears rather small and rounded. Anterior feet furnished with four toes, the posterior with three, all webbed, and terminated by strong blunt claws. No tail. Mammæ twelve. Fur coarse and thin.

The only known species of this genus is the capybara or water hog of South America (*H. capybara*, Erx., *Sus hydrochœrus*, Linn.). It sometimes measures upwards of four feet in length, and is the largest of all the Rodentia. Its habits are aquatic and gregarious. It abounds in the rivers of the Oroonoko, the Apure, and the Cassiquiare, and is much preyed on by jaguars while on shore, and by crocodiles in the water. Its flesh is excellent, and was eaten by the missionary monks during Lent along with their turtle, on the score, we presume, of its amphibious habits. Precise views of the exact nature of all mammalia are sometimes inconvenient. These animals are so numerous in many of the marshes and moist savannahs of the Llanos as greatly to injure the adjoining pastures. They browse chiefly on that kind of grass which serves best for fattening horses, called *chiguirero* or chiquiré's grass, so designated from one of the native names of the capybara. Their flesh is made into hams, and would be less disagreeable if free from the strong odour of musk with which it is impregnated. These creatures are of gentle disposition, capable of considerable attachment in a state of domestication, and not greatly fearing the human race even in their natural and unreclaimed condition. When attacked they endeavour to escape by flight; and, when overtaken, they can scarcely be said to stand upon the defensive, but as they possess great natural strength both in their incisive teeth and grinders, they have been known, in their dying agonies, or when pushed to a desperate extremity, to inflict so severe a wound as to tear the flesh from the paw of a jaguar or the leg of a horse. They were observed by Humboldt in all the great rivers, either swimming about like dogs, with the head and neck above water, or diving from the surface to escape their pursuers. They possess the power of remaining submerged for seven or eight minutes.

GENUS CAVIA, Illiger. Teeth the same in number as in the preceding genus. Feet not palmated. Only two ventral mammæ.

This genus is also believed to contain only a single species, well known throughout Europe in a domestic state under the name of guinea-pig (*Cavia cobaja*, Pallas, *Mus porcellus*, Linn., see Plate IX., figure 7 *a*). Like most reclaimed animals, it varies in its markings, the usual colours being a mixture of white, black, and reddish-brown. It is of an amazingly prolific nature, being capable of bringing forth when not more than two months old, and that same period only elapsing between the production of each brood. The number of young at a birth varies with the age of the parent, from four to twelve. It has been calculated that a single pair may prove the parent stock of a thousand in a year. The wild or native guinea-pig is supposed to be an animal of corresponding size and structure, but of a uniform reddish-grey or brown colour, paler on the under surface. It is called *aperea*, and is indigenous to the countries between the Plata and the Amazon. (See Plate IX., figure 7 *b*.) It abounds in Paraguay, and also occurs at Buenos Ayres, inhabiting brushwood by the banks of rivers, and feeding chiefly during the evening and morning twilight. A singular disparity exists in the productive powers of these animals in the natural and domestic state, the aperea being said to bring forth only one or two at a birth, and to breed not more than once a year. Some regard this as a strong fact against their probable identity; but when we consider that the teats are only two in number in each variety, we ought rather to consider the extreme fertility of the domestic kind as in a great measure the result of high and careful keeping. "Nous avons comparé," says Ant. Desmoulins, "des crânes du cobaie domestique à ceux du cobaie sauvage, et nous n'y avons pas trouvé de différence entre eux. Par-là se trouve péremptoirement réfuté tout ce qu'a dit Gall sur la cause organique de cette activité gènitale dont les extrêmes ne sont nulle part plus tranchés qu'entre les deux états sauvage et domestique de cette espèce."[1] In speaking of the domestic breed M. Desmarest observes, "qu'il ne boive jamais." Perhaps this means that they do not like water, but we can vouch for their drinking a great deal of milk. The French author adds:—"C'est un animal d'un naturel doux et docile, mais il est sans aucune intelligence, et incapable de s'attacher à son maître."[2] Now, in contradiction to the last part of the indictment, we have seen this animal exhibit great discrimination in singling out and creeping kindly into the protecting arms of a favourite and well-known individual of a pet-loving community. It is rather remarkable that the guinea-pig is never used as food in European countries, when we know that the aperea is esteemed for that purpose, and is pursued as game in its native regions.

---

[1] *Edin. Phil. Journal*, vol. ii. p. 15.

[2] See the article *Lievre* of *Dict Class. d'Hist. Nat.* t. ix. p. 378.

[3] It is curious that naturalists should differ in several important points in the history of a creature so common. "They are born covered with hair, and with their eyes open." Griffith's *Animal Kingdom*, vol. iii. p. 217. "The eyes and ears, at birth, are imperfect, the skin is destitute of hair, and the limbs unfit for locomotion." Fleming's *British Animals*, p. 21.

The animals called *agoutis* in some measure represent our hares and rabbits in the Antilles and South America. They form the genus Dasyprocta of Illiger. The common species (*Cavia agouti*, Linn.) is gregarious, living in troops of about twenty individuals. It inhabits woods, resembles a rabbit in its gait and aspect, but equals a hare in size. Its flesh is good, partaking of the qualities of these two animals combined. The agouti occurs in Guiana, Brazil, Paraguay, and some of the West Indian islands. It is said to be extremely voracious, devouring all kinds of vegetable substances, and is much attached to nuts. In a state of confinement, it will speedily gnaw its way through a door. The Patagonian cavy of Pennant and Shaw (*Das. Patachonica*), called by Azara the pampa hare, likewise belongs to this genus. It inhabits the pampas or great plains, and usually occurs in pairs. Azara was informed that this species produces its young in the burrows dug by the *viscache*. It extends far southwards into the colder countries of the New World, and was observed by Narborough and other voyagers to be very abundant in the vicinity of Port Desire, in the 47° south latitude, as well as at Port Saint Julian, some degrees farther south.

The pacas (genus *Cœlogenys*, F. Cuvier) resemble the agoutis in their teeth, but they have a small additional inner toe on the fore feet, and one (equally small) on either side of the hinder ones, making five toes to each extremity. There seem to be two species, the brown and the yellow paca (*Cel. subniger* and *fulvus*), both natives of Brazil and Guyana. They are excellent as articles of food, and Buffon and later writers have advised their importation into Europe for the uses of the table.

We shall here close our sketch of the Order Rodentia with a short notice of an animal, the exact position of which in the order has not yet been rigorously determined. We allude to the *chinchilla*, a South American species, greatly esteemed for the fineness and beauty of its fur, which forms a frequent adornment of the fair sex in Europe. Mr Bennet has remarked that, notwithstanding the extensive trade carried on in the skins of this animal, it might have been regarded till of late as almost unknown, as no modern naturalist, with the exception of Molina, had seen an entire specimen, either living or dead.[3] That author describes it as a species "of field-rat, in great estimation for the extreme fineness of its wool, if a rich fur as delicate as the silken webs of the garden spiders may be so termed. It is of an ash-grey, and sufficiently long for spinning. The little animal which produces it is six inches long from the nose to the root of the tail, with small pointed ears, a short muzzle, teeth like the house rat, and a tail of moderate length, clothed with delicate fur. It lives in burrows under ground in the open country of the northern provinces of Chili, and is very fond of being in company with others of its species. It feeds upon the roots of various bulbous plants, which grow abundantly in those parts, and produces twice a year five or six young ones. It is so docile and mild in temper, that, if taken into the hands, it neither bites nor tries to escape, but seems to take a pleasure in being caressed. If placed in the bosom, it remains there as still and quiet as if it were in its own nest. The ancient Peruvians, who were far more industrious than the moderns, made of this wool coverlets for beds and valuable stuffs."[4] A more recent observer, Schmidtmeyer, also describes it as "a woolly field-mouse, which lives under ground, and chiefly feeds on wild onions. Its fine fur is well known in Europe; that which comes from Upper Peru is rougher and larger than the chinchilla of Chile, but not always so beautiful in its colour. Great numbers of these animals are caught in the neighbourhood of Coquimbo and Copiapo generally by boys with dogs, and sold to traders, who bring them to Santiago and Valparaiso, from whence they are exported. The Peruvian skins are either brought to Buenos Ayres from the eastern parts of the Andes, or sent to Lima."[5]

A living specimen of the chinchilla was brought to England by Captain Beechy, and presented to the Zoological Society, while, at the same time, an entire skin, rendered valuable by the preservation of the skull (which never exists in the skins of commerce) was presented by Mr Collie, surgeon, to the British Museum. According to Mr Bennet, the slightest inspection of the teeth was sufficient to prove that the species could no longer be associated with the groups in which it had been previously placed, and that it was distinct in character from every other known genus of Rodentia. Geoffroy and Desmarest had previously ranged it with the hamsters (genus *Cricetus*), and Baron Cuvier having never seen its teeth, was uncertain whether it was most allied to the guinea-pigs, the lagomys, or the rats. But the inspection of the specimens above alluded to has shewn that it possesses two incisives and eight molars in each jaw, or twenty teeth in all. The form of the head resembles that of a rabbit; the eyes are full, large, and black; and the ears (in this differing from Molina's description, already quoted) are broad, naked, rounded at the tips, and nearly as long as the head. There are four short toes, with a distinct rudiment of a thumb on the anterior feet; and the posterior are furnished with the same number, three of them long, the middle more produced than the two lateral ones, and the fourth external to the others, and placed far behind. A second specimen has been since added to the collection of the Zoological Society of somewhat larger size and rougher fur.[6]

Order V.—EDENTATA, Cuv.

The term edentate, or toothless, must not be construed literally in relation to the truly singular groups which constitute the present order. The front teeth are absent, but

Edentata.

the armadillos have both canines and molars,—the latter, indeed, so numerous as to be surpassed only by those of the cetaceous genus *Delphinus*. The osteology of this order is the only portion of their structure with which we are well acquainted, and we owe that knowledge to the beautiful memoir of Baron Cuvier.[1] But we know with what singular fidelity the skeleton, though itself essentially inert, represents, by the form and amalgamation of its parts, the supervening modifications of the more active organs, that is, those of the nervous, sensitive, and digestive systems. In relation to almost all the actions which result from those systems, our present order is not only one of the most widely separate from other Mammalia, but also presents the greatest disparity between several of its own genera, as compared with each other. These genera, it has been observed, though connected together in spite of obvious differences, by several heteroclyte characters, and appearing to be, as it were, the work of a particular conception, are by no means the products of one common country, but almost each group is characteristic of some separate great division of the globe, such as the southern parts of Africa and America, the Indian Archipelago, or New Holland. It is difficult to state any character belonging to the entire order, although the great size of their claws, embracing all the extremity of the toes, and more or less approaching the nature of hoofs, is perhaps among the most prevalent. Their movements may be characterized as slow and inactive. Some climb trees, others dig burrows, while the habits of a few are amphibious. Their food varies in the different genera. None are strictly or fiercely carnivorous, but several devour insects, and shew no distaste for flesh. Many indulge in a herbivorous diet. Baron Cuvier divides the order into three tribes, as follows.

TRIBE 1ST, TARDIGRADA.

We here place those singlar animals of the New World, commonly called sloths,—genus BRADYPUS, Linn. They are distinguished by the shortness of the face, by the cylindrical form of the molars (four on each side above, and three below), and the sharp and lengthened shape of the canines. (See Plate X., figure 3.) The toes, varying as to amount in different species, are incased within the skin as far as the base of the claws, which are long and arched, and in a state of repose are kept bent beneath the palm of the hand, or sole of the foot. The hind feet are articulated obliquely on the leg, and thus act as supports, chiefly by their external margins. "Les phalanges des doigts," says Cuvier, "sont articulées par des ginglymes serrés, et les premières se soudent à un certain âge aux os du métacarpe on du métatarse: ceux-ci finissent par se souder ensemble faute d'usage;"[2] and to this inconvenient (or we should rather say peculiar) structure of the extremities, may be added that of their disproportionate respective lengths. The arm and fore-arm are much longer than the thigh and leg, so that when they walk they are obliged to draw themselves along upon their elbows. The pelvis is so broad, and the thighs are so directed laterally, that the knees cannot approximate. "Ils se tiennent sur les arbres," says Cuvier rightly, for their structure is entirely suited to arboreal habits;—but when he adds, "et n'en quittent un qu'après l'avoir dépouillé de ses feuilles, tant il leur et penible d'en gagner un autre," we must correct the sentiments of the European philosopher by the experience of a practical observer. Mr Waterton states, that as he was one day crossing the river Essequibo, he saw a large two-toed sloth upon the ground. How it came there nobody could tell. Although the trees were not twenty yards from him, he could not make his way even that short distance before the party landed and overtook him. He immediately threw himself upon his back, and gallantly defended himself with his fore-legs. Mr Waterton humanely allowed him to hook himself to a long stick, by which he conveyed him to a high and stately mora tree. This he ascended with great rapidity, and then went off in a lateral direction, by catching hold of the branches of another tree, and so he proceeded towards the heart of the forest, and was soon lost to view. The sloth, in truth, is the most sylvan of quadrupeds. It is produced, it lives, and it dies among trees, and though unequal to cope with John Gilpin in speed, it yields not to his namesake in love of forest scenery. "The sloth," says our author, "is the only known quadruped which spends its whole life from the branches of trees, suspended by his feet. I have paid uncommon attention to him in his native haunts. The monkey and squirrel will seize a branch with their fore feet, and pull themselves up, and rest or run upon it; but the sloth, after seizing it, still remains suspended, and suspended moves along under the branch, till he can lay hold of another. Wherever I have seen him in his native woods, whether at rest, or asleep, or on his travels, I have always observed that he was suspended from the branch of a tree; and when his form and anatomy are considered, it will appear evident that he cannot be at ease in any situation where his body is higher or above his feet."[3] One of the great objects of the creation seems to be to multiply the enjoyments of animal life,—an object which can only be attained by a vast diversity in structure and instinct. In the case of the sloth, as in all other cases, structure and instinct accord, and we may therefore fairly infer, notwithstanding what Buffon and others have *composed* regarding his miserable and degraded existence, that his peculiar mode of life is accompanied by a corresponding share of pleasure and advantage. No animal is organized for wretchedness.

Edentata.

Few species of the genus are as yet distinctly known, and these few offer among themselves a considerable disparity of structure in several important particulars, such as the number of the ribs, and the form of the cranium. The three-toed species, which are furnished with a short tail, form the genus ACHEUS of F. Cuvier. Of these the *aï*, or three-toed sloth (*Brad. tridactylus*, Linn., see Plate X., fig. 2.), is the only animal hitherto supposed to possess nine cervical vertebræ. We have already alluded to the more recent opinion, that in this respect it forms no exception to the usual rule.[4] The *Unau*, or two-toed species (*B. didactylus*, Linn., Ibid., fig. 4), is, according to Cuvier, "un peu moins malheureusement organisé que l'Ai," in other words, something different in its habits of life, renders necessary a less anomalous form. All these animals are believed to be very tenacious of life. They will hang long to the branch of a tree after being mortally wounded. "Delalande aidé de son domestique, a inutilement essayé pendant une demi-heure d'étrangler un Aï avec une corde de la grosseur du doigts; l'animal ne cessait d'étendre et de ramener ses bras en crochets sur la poitrine par intervalles, ce qu'il fit encore pendant plusieurs heures au fond d'un tonneau d'alcohol où on le tint ensuite submergé. Pison avait disséqué vivante une femelle pleine d'unau. Elle se remuait encore en totalité et contractait ses pieds longtemps après l'arrachement du cœur et des viscères."[5] We conclude by observing that sloths are entirely herbivorous, feeding chiefly on leaves, especially those of *Cecropia peltata*.

TRIBE 2D, EFFODENTIA.

In this tribe the muzzle is elongated. The teeth are of the molar kind only (and in some even these are wanting).

[5] *Dict. Class. d'Hist. Nat.* t. ii. p. 483.

The first generic group is that called Dasypus by Linnæus, which we name armadillo. Their teeth are feeble, simple, and cylindrical, and range in different species from 28 to 68. Their most remarkable character consists in their being covered by a defensive armour, or kind of osseous shell, divided into polygonal scales arranged in numerous transverse bands, covering head, body, and oftentimes the tail. The ears are large, the claws strong, and varying in number with the species. The tongue is smooth, and but slightly extensile. A few scattered hairs occur between the scaly plates, but these creatures can scarcely be said to have any fur. They dig burrows, and live partly on a vegetable regimen, partly on insects, reptiles, worms, and animal remains. Their stomach is simple, and the cœcum is absent. They are all natives of the warmer and temperate parts of America. The females are very prolific.

As we cannot here describe the species, nor even indicate the minor groups into which recent naturalists have divided the original genus, we shall here give a short extract in illustration of their general habits.[1] We quote from Mr Waterton, to whom naturalists are greatly indebted for many interesting elucidations of the history of the rarer animals of South America. "The armadillo burrows in the sand like a rabbit. As it often takes a considerable time to dig him out of his hole, it would be a long and laborious business to attack each hole indiscriminately, without knowing whether the animal were there or not. To prevent disappointment, the Indians carefully examine the mouth of the hole, and put a short stick down it. Now if, on introducing the stick, a number of musquitos come out, the Indian knows to a certainty that the armadillo is in it; and *vice versa*, wherever there are no musquitos in the hole, there is no armadillo. The Indian, having satisfied himself that the armadillo is there, by the musquitos which come out, immediately cuts a long and slender stick, and introduces it into the hole; he carefully observes the line the stick takes, and then sinks a pit in the sand to catch the end of it; this done, he puts it farther into the hole, and digs another pit; and so on, until at last he comes up with the armadillo, which had been making itself a passage in the sand till it had exhausted all its strength through pure exertion. I have been sometimes three quarters of a day in digging out one armadillo, and obliged to sink half a dozen pits, seven feet deep, before I got up to it. The Indians and negroes are very fond of the flesh, but I consider it strong and rank. On laying hold of the armadillo, you must be cautious not to come in contact with his feet; they are armed with sharp claws, and will inflict severe wounds: when not molested, he is harmless and innocent. The armadillo swims well in time of need, but does not go into the water by choice. He is very seldom seen abroad during the day; and when surprised, he is sure to be near the mouth of his hole. Every part of him is well protected by his shell, except his ears. In life, this shell is very limber, so that the animal is enabled to go at full stretch, or roll himself up into a ball, as occasion may require."[2]

We knew little of the actual history of the armadillos, or of their amount of species, till the time of Azara, who describes eight different kinds, one of which (*Das. giganteus*) measures above three feet in length. They were supposed to feed exclusively on vegetable substances, till the Spanish author observed that they were both insectivorous and carnivorous. The direction of their burrows shew that they pursue the ant-heaps, and these laborious insects quickly diminish in their neighbourhood. The great species just named (which belongs to the genus Priodontes of F. Cuvier, distinguished by the great size of its claws, and the enormous number of its teeth,—about 90 in all) feeds on carcasses, and when a human being happens to be buried beyond the usual precincts of the sepulture, and in a district where this animal occurs, the grave is covered by strong double boards, to prevent the disinterment of the body. They also prey on birds and their eggs, as well as on lizards and other reptiles. They are themselves eaten both by native Indians and by Spanish tribes. As an example of the genus we have figured the Encoubert, or six-banded armadillo (*Das. sexcinctus*, Linn., see Plate X., fig. 9), a species distinguished from all the others by possessing a pair of small teeth upon the incisive bone. It measures about a foot and a half in length from the snout to the insertion of the tail. The latter part is round, about half the length of the body, and is ringed only at its base. The cuirass is composed of six or seven moveable bands, formed of large, smooth, rectangular pieces, longer than broad.[3] This animal runs swiftly, and burrows with great ease. It possesses, in spite of its scaly armour, the singular faculty of so pressing and expanding itself upon the surface of the ground, as to become three times broader than high. It is extremely common in Paraguay.

We may here notice a very singular animal of modern discovery, of the natural habits of which our information is as yet extremely scanty, but which partakes of many of the characters of the armadillos. We allude to the *Chlamyphorus truncatus* of Dr Harlan. (See Plate X., figure 1.) It is a subterranean species from Mendoza, in the interior of Chili, so well represented on the plate referred to, as to save us the necessity of descriptive details. The animal was obtained in a living state, but survived in confinement only a few days. Its habits are said to resemble those of the mole, and it is reputed to carry its young beneath the scaly covering of its body. Baron Cuvier states that it has "dix dents partout,"[4] while its original describer mentions only eight on each side (all molars), that is, sixteen in each jaw.[5]

Genus Orycteropus, Geoff. The only known species of this genus is an animal peculiar to Africa, called the Cape ant-eater (*Or. Capensis*). It is of large dimensions, measuring between three and four feet in length, exclusive of the tail, which is nearly two feet long. Its grinders amount to six on each side of both jaws, or twenty-four in all, and are distinguished by a peculiar structure, being in the form of solid cylinders, traversed throughout their length by an infinity of little canals resembling the interior pores of canes. Its habits are nocturnal and subterranean, and its food consists of ants and termites, which it seizes with its long glutinous tongue, after having disarranged their dwellings with its paws. The ant-eaters properly so called, belong to the following genus, and are peculiar to America, so that the species just noticed may be regarded merely as their African representative. Its flesh is used as food, and is indeed held in considerable estimation both by European and Hottentot, notwithstanding the strong odour of formic acid with which it is infected.

Genus Myrmecophaga, Linn. Teeth entirely wanting. Head more or less elongated, and terminated by a slender muzzle and a narrow mouth. Eyes and ears small, the latter rounded. Tongue very long, cylindrical, and capable of extension. Toes (varying in number with the species) always united as far as the base of the claws, which are large and strong. Tail very long, sometimes prehensile and comparatively bare, sometimes covered with lax depending hairs.

[2] *Wanderings*, p. 183.

[3] A different mode of counting the bands of this and other species has led to some confusion in their synonymy. *D. sexcinctus* and *octodecimcinctus*, Linn. are one and the same, and correspond to the *Tatou poyou* of Azara.

[4] *Règne Animal*, t. i. p. 229.

[5] See *Annals of the New York Lyceum of Natural History*, vol i., and *Zoological Journal*, No. vi.

This genus consists of the true ant-eaters, all of which are natives of South America, and occur chiefly in the countries bounded on the south-east by the Rio de la Plata, and on the north by the Oroonoko. Naturalists are tolerably well acquainted with at least three species. They prey almost exclusively on ants and termites, which they take by means of their long, extensile, gluey tongues, aided, as excavating implements, by their vigorous claws. Like the sloths, there exists among themselves a considerable disparity of structure,—the small two-toed species being provided with strong clavicles, attached to the sternum, while in the larger species these parts are entirely wanting. One of the most notable features of the ant-eaters consists in the lengthened, cylindrical, tunnel-shaped character of the head, which almost resembles that of the long-billed birds, such as snipes and woodcocks. This is caused chiefly by the great prolongation of the jaws, of which the upper (in the species called *Tamandua*) is more than twice the length of the cranium. If these long jaws were to open at the same angle as in most mammiferous animals, the gape or separation of the terminal portions would be proportionally greater than in any other species; but, as it happens, the opening of the mouth is in fact the most restricted with which we are acquainted. This is owing to the jaws being surrounded throughout their entire extent by the skin, there being only a very small terminal mouth, measuring scarcely a fifteenth part of the length of the maxillæ. The muscles of the lower jaw are, moreover, so extremely feeble, as to be almost unable to produce any compression. They seem to collect their food entirely with their tongue, and may be presumed to swallow it without mastication, like the majority of birds and fishes. The ant-eaters, of all the Mammalia, are those of which the temporal fossæ and zygomatic arches are the most effaced. The bones of the nose occupy almost the half of the length of the upper portion of the head. The ribs of these animals are so broad, as to leave scarcely any intermediate space between them.

The great ant-eater (*Myr. jubata*), though low of stature, is an animal of almost gigantic extent, sometimes measuring seven feet from the muzzle to the end of the tail. It has four toes to the anterior feet, and five to the posterior. Its tail is garnished, from base to tip, with very long hair. It seems singular that so large and robust a creature should support itself solely on ants; but we must bear in mind the multitudes of those minute insects which occur in South America. In captivity it may be fed on crumbs of bread, meal, flour and water, &c. A living specimen, brought a good many years ago into Spain, ate readily of raw meat minced, and was said to swallow from four to five pounds a-day.[1] How many ants would be required to equal that amount? This species possesses great strength in its legs and paws, and is said to defend itself successfully against the attacks of the largest feline animals, such as the jaguar and other beasts of prey. It is even held in great dread by the Indians, who however much they may have disabled it, never approach it closely till it is entirely dead. When it seizes an animal with its fore-paws, it hugs it tightly to its body, and retains its grasp so tenaciously as to kill its enemy either by pressure or starvation. It does not climb trees.

The species known under the name of Tamandua (*Myr. tamandua*, Cuv., *M. tetradactyla* and *tridactyla*, Linn.), is not more than half the size of the preceding, and differs in its prehensile and almost naked tail, by which it is assisted in climbing trees. Azara supposed that, in addition to the usual insect food, this species eats wild bees and honey. It smells strongly of musk. The little ant-eater (*M. didactyla*, Linn., see Plate X., figures 5 and 8) is rather an elegant animal. Its body measures little more in length than six inches, and, besides the great disparity of size, it is distinguished from the two preceding species by having only two claws to the fore feet and four to the hinder ones. It is covered by a beautiful soft fur, of a very pale yellowish-brown colour. It inhabits the woods of Guyana and Brazil, dwelling habitually on trees, and preying on ants and other insects.

GENUS MANIS, Linn. In this genus also the teeth are entirely wanting. The body is extremely elongated, low upon the legs, and covered by strong corneous scales. The muzzle is very long, the mouth small and terminal, the tongue of remarkable length, round and extensile. All the feet have five toes, armed with strong talons. The tail is very long, covered with scales, and as broad at its base as the termination of the body.

The entire range of the animal kingdom scarcely presents us with species of a more marked and peculiar aspect than the manis tribe or *pangolins*. Instead of hair they are covered by a scaly armour, composed of triangular plates, placed upon each other like slates or tiles; and this remarkable character, combined with their attenuated form, gives them so much the appearance of reptiles, that they are often designated as *scaly lizards*. (See Plate X., figures 6 and 7.) We possess no very detailed knowledge of their natural history. They seem to be inoffensive creatures, feeding, like the ant-eater, on insects, especially ants, which they collect by thrusting their long insidious tongue into the dwellings of these industrious labourers. Three species are described by systematic writers, and of these one inhabits continental India, another occurs in Java, and a third is native to Senegal and the coast of Guinea.

TRIBE 3D, MONOTREMA.

The term by which this tribe is designated was first bestowed by Geoffroy St Hilaire, and is now very generally adopted by naturalists. It applies to a small number of species discovered in New Holland in comparatively recent times, and characterized by a general organization, certainly conformable to that of other mammalia, but with modifications so remarkable and anomalous, that their true position in the animal kingdom (the very class to which they belong), is still a disputed point. The apparent absence of mammæ, and their supposed oviparous nature, were these two circumstances satisfactorily ascertained, would either remove them from the ordinary class of quadrupeds, or render necessary an alteration in the technical definition of that class. In our present tribe only two genera are as yet included, viz. ECHIDNA and ORNITHORHYNCHUS. Latreille was of opinion that these should form two distinct orders, an arrangement which has not been adopted, but which possesses the advantage of shewing that they greatly differ from each other,—an inference not deducible from Sir Everard Home's mode of combining them in a single genus. Shaw placed Echidna with the ant-eaters, and as connecting these with the porcupines; while he expressed his opinion that Ornithorynchus (his genus *Platypus*), should follow Myrmecophaga. This arrangement, in fact, approaches very close to that adopted by Baron Cuvier.

The monotremous tribes exhibit several peculiarities in their osteological structure, by which they are further allied to the class of birds. Such, for example, is a kind of clavicle common to both shoulders, placed in front of the ordinary clavicle, and analogous to the furcula of the feathered tribes. Besides the five claws on each foot, the males bear a spur on their hind legs, resembling that of a cock, but pierced by a canal capable of transmitting a liquid of a venomous or inflammatory quality, secreted by a peculiar gland.[1] But however anomalous these and other characters may be, when we consider their quadrupedal form, their hairy covering, their lungs freely suspended, the existence of a diaphragm, the rudiments of teeth, and the general agreement of the skeleton with that of other mammiferous animals, we can scarcely hesitate as to the class to which they belong.[2] Their agreements with the Mammalia are numerous and striking, and deduced from the most important organs, while their disagreements are few, and deduced for the most part from characters not of the highest value. We shall conclude these meagre generalities with the words of Baron Cuvier: "Avec les formes extérieures et le poil des mammifères; avec leur circulation, leur cerveau, leurs organes des sens, et une grande partie de leurs organes du mouvement; avec le bassin des Didelphes, les Monotremes ressemblent à beaucoup d'égards, aux oiseaux et aux reptiles par leur épaules et par les organes de la generation; ils manquent de mamelles et paraissent assez vraisemblablement produire des œufs ou quelque chose d'equivalent, au lieu de mettre au jour des petits vivans. Ils semblent vouloir échapper à nos classifications par leur ostéologie comme par leurs autres rapports. On ne peut comparer celle de leur tête à celle d'aucun des ordres de Mammifères; cependant c'est une vraie tête de Mammifère et non d'ovipare d'aucune classe."[3]

---

[1] Shaw's *General Zoology*, vol. i. p. 168.

GENUS ECHIDNA, Cuv. Teeth entirely wanting, but their functions partly supplied by several rows of small spines upon the palate, directed backwards. Muzzle long, slender, terminated by a small mouth, containing an extensile tongue. Body short and rounded, covered by many strong sharp spines. Legs short, each foot furnished with five strong claws, fit for digging. Tail very short.

Only two species of this genus have been as yet discovered,—the *E. hystrix*, which occurs in the vicinity of Port Jackson, and is almost entirely covered by strong spines, and the *E. setosa*, a native of Van Diemen's Land and the islands in Bass's Straits, characterized by fewer species, and a more ample coat of hair. (See Plate XI., figure 1.) Some observers incline to consider them as varieties of the same species, resulting from a difference in age.[4] Both animals are nearly of the size, and somewhat of the aspect, of a hedgehog. They feed on insects, and burrow under ground with great strength and celerity, their feet and claws being admirably adapted to subterranean purposes. It is even said that they will make their way beneath a wall, or under a pretty strong pavement. During these exertions their bodies become greatly lengthened, so as to present a very different appearance from that of their ordinary state. They keep much under ground during dry weather, and move about chiefly during the rains. They are capable of supporting a long continued abstinence, and seem subject to a kind of numbness or peculiar stiffness (*engourdissement*), which will sometimes continue for upwards of eighty hours, and is frequently renewed when they are retained in captivity.[5]

GENUS ORNITHORHYNCHUS, Blumenbach. *Platypus*, Shaw. This genus differs from the preceding, in having two fibrous molar teeth placed in the gums on each side of both jaws. The muzzle is prolonged into a broadish flattened beak, greatly resembling that of a duck. The head is small and round, with minute eyes, and no external ears. The nostrils are round, close to each other, and placed near the extremity of the upper mandible or jaw. The tongue is in some measure double,—there being one within the beak, beset with villosities, and bearing another at its base, of a thicker form, with two small fleshy anterior points. The legs are very short, directed laterally, the anterior and posterior very distant from each other, owing to the comparatively lengthened form of the body. Each foot has five toes, those of the anterior extremities of nearly equal size, slender, separate, furnished with flattened nails, united by a peculiar membrane which projects beneath them; the posterior toes united as far as the nails. Tail rather short, broad at the base. The body is covered with hair.

Of this very singular genus it does not appear that more than a single species has as yet been ascertained,[6]—the *Ornithorhynchus paradoxus* of modern writers, first described by Dr Shaw under the name of *Duck-billed Platypus*.[7] It is an animal of a very peculiar aspect (see Plate XI., figure 2), of amphibious habits, and a native of New Holland, where it inhabits marshes, and the banks of rivers, especially in the neighbourhood of Port Jackson. The general belief is, that it lays eggs. We think, however, that that fact has as yet been rather inferred than demonstrated; and it is certainly singular that it should not have been proved in those districts where the species is so often met with, and where so extraordinary a circumstance must have excited a corresponding degree of curiosity and attention. The following detailed particulars were published some time ago in an Italian periodical, but without any indication of the source from which they were derived: "The ornithorhynchus inhabits the marshes of New Holland. It forms, among beds of reeds by the water-side, a nest composed of hair or wool, and intermingled roots, in which it deposits two white eggs, smaller than those of our domestic poultry; on these it sits a long time, hatching them like a bird, and refusing to leave them unless threatened by a very formidable foe. It appears that during all this time it eats neither seeds nor herbs, but contents itself with slime or mud; at least nothing more is found within it. When the ornithorhynchus plunges under water, it remains but a short time submerged, and comes soon to the surface, shaking its head like a duck. It walks, or rather creeps, along the margins of the marshes with considerable quickness; its movements are prompt, and its sight so excellent as to render its capture difficult. It usually employs only one nostril in respiration. It scratches its head and neck, like a dog, with one of its hind legs. It attempts to bite when taken, but can inflict no injury, owing to its soft and feeble beak. The male alone is armed with a spur upon the hinder legs, and he employs that weapon against his aggressors. The wound which he inflicts produces inflammation and a violent pain, but there is no instance of its having ever occasioned death."[1] There is an appearance of truth in the circumstantial mode in which the preceding details are narrated, and we therefore regret the more that they should have appeared anonymously. The testimony borne to the oviparous nature of the animal in question accords with the reported belief of the natives, and with the researches of Hill and Jamison. "The female," says the last named observer, "is oviparous, and lives in burrows in the ground, so that it is seldom seen either on shore or in the water. The males are seen in numbers throughout our winter months only, floating and diving in all our large rivers; but they cannot continue long under water. I had one drowned by having been left during the night in a large tub of water. I have found no other substance in their stomachs than *small fish and fry*. They are very shy, and avoid the shot by diving, and afterwards rising at a considerable distance."[2]

---

[1] "I cannot," says Sir John Jamison, "avoid relating to you an extraordinary peculiarity which I have lately discovered in the Ornithorhynchus paradoxus. The male of this wonderful animal is provided with spurs on the hind feet or legs, like a cock. The spur is situated over a cyst of venomous fluid, and has a tube or cannula up its centre, through which the animal can, like a serpent, force the poison when it inflicts its wound. I wounded one with small shot; and, on my overseer's taking it out of the water, it struck its spurs into the palm and back of his right hand with such force, and retained them in with such strength, that they could not be withdrawn until it was killed. The hand instantly swelled to a prodigious bulk; and the inflammation having rapidly extended to the shoulder, he was in a few minutes threatened with locked jaw, and exhibited all the symptoms of a person bitten by a venomous snake. The pain from the first was insupportable, and cold sweats and sickness of stomach took place so alarmingly, that I found it necessary, besides the external application of oil and vinegar, to administer large quantities of the volatile alkali with opium, which I really think preserved his life."—Extract from letter dated Regentville, New South Wales, September 10. 1816, published in *Linn. Trans.*, vol. xii. p. 584. See also Dr Knox's *Observations on the Anatomy of the Ornithorhynchus paradoxus*, in *Memoirs of the Wernerian Society* (for 1823–4), vol. v. p. 26 and p. 144.

[6] In this opinion we coincide with Oken, Meckel, and Geoffroy St Hilaire. Desmarest, Macgillivray, Vander Hoeven, Peron and Lesueur, and other writers, have described what they regard as one or more species distinct from the common kind. We apprehend that these authors, in the absence of an extensive series of specimens, have attached too much importance to certain *individual* variations.

[7] *Naturalist's Miscellany*, pl. 385.

ORDER VI.—PACHYDERMATA.

In entering upon the consideration of this interesting order, we may remind the reader that all the terrestrial Mammalia are divisible into two great secondary groups, the unguiculated or nailed quadrupeds, and the ungulated or hoofed quadrupeds. The former series may be said to terminate with the Edentata, which themselves approach the ungulated tribes in the great size of their claws, and the hoof-like fashion in which these embrace the extremities of the toes. They still, however, possess the faculty of being bent, or otherwise varied in their motion, for the purposes of seizure, excavation, &c. It is the absence of that faculty which characterizes the hoofed animals properly so called; they want the clavicle, and their anterior extremities are always in a state of pronation, being available only for the purposes of support and of locomotion, but not for collecting their food, or for any other kind of manipulation. They all browse on vegetable substances, and their bodily forms, as well as their modes of life, are less varied than those of the unguiculated orders.

The great ungulated or hoofed division is itself partitioned into two groups, one of which consists of the ruminating tribes (order PECORA or RUMINANTIA), and the other of certain thick-skinned genera, called PACHYDERMATA,—our present order. Of these two orders it will be readily perceived that the former is established upon organic peculiarities of the highest importance, and is therefore in a great degree natural and well composed, while the constituents of the latter agree principally in the negative character of not being ruminant, and exhibit among themselves so great a range and diversity of structure and character, as to present a much less natural combination. We find, accordingly, in examining the different genera, that their toes vary (externally) from one to three, four, and five; that their teeth are sometimes of three kinds, sometimes of only two; that their skin, generally bare, is occasionally covered by close or even shaggy hair; that their stomach, in some cases simple, is in others divided into several pouches; that the size of certain species is small, while that of others attains to the most gigantic dimensions; and that while certain minor groups seem nearly allied to the ruminants, others are broadly distinguished by numerous anomalies of organization, some of which point them out as among the most remarkable species of the animal kingdom. In a word, the pachydermatous order consists of the small sized living Daman, and the gigantic and now extinguished Mastodon,—of the swift and slender limbed horse, and the short-legged sluggish rhinoceros,—of the savage boar, and mild-eyed elephant. The great differences which exist in the genera now named have occasioned the grouping of this order into several families, which some authors are inclined to view rather in the light of distinct orders.[3] We certainly think that the removal of the genus Equus (which Illiger and others have classed as a separate order under the title of SOLIDUNGULA) would enable us to simplify our definition of the pachydermous tribes.

FAMILY 1ST.—PROBOSCIDEA.

This family includes of living creatures (and with the fossil species we are not concerned) the genus ELEPHAS alone. The skeleton exhibits five complete toes, but so encrusted in a callous skin which surrounds the foot, that only the nails are visible, attached, as it were, to the margins of a seeming hoof. The canine teeth, and incisives, properly so called, are wanting, but in the incisive bones are implanted a pair of tusks, projecting much beyond the mouth, and sometimes attaining an enormous size. The necessary dimensions of the alveoli of these peculiar teeth, as Baron Cuvier has remarked, render the upper jaw so high, and so shorten the bones of the nose, that the nostrils, in the skeleton, occur towards the upper portion of the face, although in the living animal they are prolonged under the form of a long, gradually attenuated, cylindrical, trunk or proboscis, composed of several thousand small muscles, so variously interlaced as to produce a great diversity of motion, endowed with an exquisite sense of touch, and terminated by a small finger-formed appendage. By means of this admirable organ the elephant is possessed of almost as much address as the ape receives from the human-like structure of its hand. Its exquisite uses are so frequently exhibited in menageries, that we need scarcely expatiate upon the subject. The head, though of enormous size, is rendered comparatively light by the cellular structure of a large portion of the cranium. There are no incisive teeth in the lower jaw; the grinders are two on both sides of each jaw; making the total number ten, including the tusks. The stomach is simple, the cœcum enormous, the mammæ only two, their position pectoral.[4]

As the GENUS ELEPHAS contains all the living species of the family, the preceding characteristics may be regarded as generic. The distinctive character of the teeth consists in the molars being composed of a certain number of vertical plates, each formed of an osseous substance, enveloped by enamel, and connected together by a third or cortical matter. These teeth succeed each other not vertically, as the second molars of the human race succeed the milk-teeth, but from behind forwards, in such a manner that in proportion as one grinder becomes used it is pushed forward by its successor; and thus there is sometimes two, sometimes only one on each side. The first teeth have few plates, the succeeding ones a greater number; and the molars are said to be sometimes changed as often as eight times, while the tusks or great incisives are only once renewed. There are only two species known to naturalists of these gigantic creatures.

[3] See *Dict. Class. d'Hist. Nat.* t. xii. p. 579.

[4] *Règne Animal*, t. i. p. 238.

The African elephant (*G. Africanus*) is easily distinguished from the Asiatic species by his rounder head, more convex forehead, much larger ears, and the lozenge-marked surface of his grinders. His tusks are also longer, and those of his female are described as equally great with his own, whereas the female of the Asiatic elephant has very small tusks. He inhabits a wide extent of Africa from Senegal to the Cape, and abounds in the forests of the interior. That the African elephant has not in modern times been rendered serviceable to man, we cannot think arises from any defect in the wisdom or docility of his disposition, but rather from a difference in the social and political conditions of the human tribes of Africa, and their inferior civilization. It is known that the ancient Carthaginians made use of elephants, which, so far as our information extends, there is no reason to believe were otherwise than of African origin; in like manner as the Asiatic variety was used by Porus and the Indian kings. It is not yet clearly ascertained whether the individuals of the eastern shores of Africa are specifically the same as those of the interior and western districts, or whether they do not exhibit a closer approximation to the Asiatic species. We may observe, that the size of both the African and eastern elephant has been much exaggerated. Dr Hill, for example, asserts that when full grown they will measure from seventeen to twenty feet in height. One-half of the latter dimension is probably nearer the truth, even for an individual of more than usual size, and twelve feet may be stated as an extreme height. The African, however, are alleged (by travellers though not by systematic writers) to be larger than those of Asia. Major Denham, for example, while journeying to the Schad, saw elephants so enormous that he calculated their height at sixteen feet. These, however, he had no opportunity of measuring; but another which was killed in his presence was found to be nine feet six inches from the foot to the hip-bone, and three feet from the latter to the back; that is, twelve feet and a half in all, or more than twice the height of the tallest races of mankind. When we consider, that even in proportion to its height, the elephant is an animal of enormous bulk, and of the most massive proportions, we may conceive what an enormous mass of flesh and bone its rugous coat must usually contain. A large individual weighs from six to seven thousand pounds, and it may easily be imagined that when travelling through the forest with any special object in view, he must force his way through all intervening obstacles more after the manner of a modern locomotive engine, than of any mere animal force of which we have an accustomed conception.

> "Trampling his path through wood and brake,
> And canes which crackling fall before his way,
> And tassel-grass, whose silvery feathers play,
> O'ertopping the young trees,
> On comes the elephant to slake
> His thirst at noon in yon pellucid springs.
> Lo! from his trunk upturn'd, aloft he flings
> The grateful shower; and now,
> Plucking the broad-leav'd bough
> Of yonder plume, with waving motion slow,
> Fanning the languid air,
> He waves it to and fro."[1]

Of the Asiatic elephants (*Eleph. Indicus*, see Plate XI., fig. 3) those of Ceylon are among the most celebrated. Indeed, the torrid zone seems the most favourable for the production of the largest races; for although elephants occur along the coast of Malabar as far north as the territories of Coorgah Rajah, these, according to Mr Corse (Scott) are inferior to the breed from Ceylon. Those of China, where they seem to be used rather as an appendage of imperial greatness than as beasts of burden, are described as smaller than those of more southern regions, and of a lighter hue. A few are, however, said to have bred to the northward of the tropic; and we may add, that elephants appear to have been very anciently known even in remote parts of the Chinese empire.[2] As Kublai Khan, one of the conquering heroes of the thirteenth century, subdued Ava and other southern provinces, where elephants are known to have abounded, and where they were opposed to his armies in battle, it is probable that he then added those gigantic and imposing animals to his establishment, and conveyed them to the more northern parts of his great Tartarian empire, which included a large portion of what we now designate by the name of China. A few are still kept by the emperors of the reigning dynasty.[3]

It is to the Asiatic species that most of the anecdotes apply, as recorded in our systematic works and books of travels.[4] Although generally regarded as the "wisest of beasts," it is alleged by some to owe much of its apparent sagacity to that admirable instrument its proboscis, by which it is enabled to perform many actions which the canine race, though probably equal in wisdom, cannot achieve in consequence of their different, if not more defective, organization. "Après," says Baron Cuvier, "les avoir étudiés long-temps, nous n'avons pas trouvé qu'elle (l'intelligence) surpassât celle du chien ni de plusieurs autres carnassiers."[5] Still we think it is demonstrable both from ancient record and modern observation, that the elephant is most highly gifted for an irrational being, and that it generally retains its finer natural instincts even in conjunction with those artificial acquirements which in several other sagacious species seem to deaden or destroy the influence of pure instinctive feeling.

We have already stated our opinion that the size of the elephant is usually exaggerated. Mr Scott of Sinton, whose authority is frequently quoted, and deservedly valued on such points, has stated, in relation to the Asiatic species, that he never heard of more than a single instance of its exceeding the height of ten feet. The following are the proportions which he gives of a fine male belonging to the Vizier of Oude:—

	Feet.	Inches.
From foot to foot over the shoulder, . . .	22	10½
From the top of the shoulder, perpendicular height, ...	10	6
From the top of the head when set up, . .	12	2
From the front of the face, to the insertion of the tail, ...	15	11

[4] As our restricted space prohibits an ampler exposition, we beg to refer the reader to a very accessible volume (in the *Library of Entertaining Knowledge*) entitled *The Menageries*, vol. ii., where a complete account is given of the ancient and modern history of elephants.

[5] *Règne Animal*, t. i. p. 239.

Nothing, indeed, is more deceptive than the dimensions of an animal which, obviously exceeding in size whatever living creature we have been previously accustomed to, has yet been unsubjected to actual measurement, for our astonishment magnifies the real size. Thus a celebrated elephant belonging to the Nabob of Dacca, which was generally reported to be fourteen feet high, and which even Mr Scott's practised eye estimated at twelve, was found by measurement not to exceed ten feet. Those from Pegu and Ava (as well as the Ceylonese) are, however, of greater size than those of Hindostan. There is the skeleton of an elephant in the museum of St Petersburgh, presented by the King of Persia to the Czar Peter, which measures above sixteen feet in height, but we have no doubt that some portion of this prodigious stature is owing to the mode in which the bones have been articulated in the *setting up*, and the more or less natural curvature of the spine. A new born elephant usually measures about thirty-five inches high, and he is said to grow eleven inches the first year, eight the second, five the fifth, three and a half the sixth, and two and a half in the seventh year. He takes from twenty to thirty years to attain his full growth, and has been alleged to live for a couple of centuries. There are authentic instances of elephants having been kept in a domestic state for a hundred and thirty years. The female is capable of breeding after her fifteenth year. She produces a single young one at a birth, after a gestation of from twenty-two to twenty-three months.

Elephants in this country are usually fed on hay and carrots, and the quantity of food which they consume is enormous. Those of the Emperor Akbar had each a daily allowance of 200 pounds in weight, with an additional supply of ten pounds of sugar, besides rice, milk, and pepper; and during the sugar-cane season each was provided daily with 300 canes. The Mogul princes are known to have kept up their stud of elephants at a vast expense; and according to Pliny, even the Romans, a people so addicted to extravagance, found the sustaining of the Carthaginian elephants captured by Metellus so costly, that they were afterwards slain in the circus. Yet, according to Ælian's account, less rigid economy prevailed in the days of Germanicus. His elephants were exhibited in the arena, reposing on splendid couches, adorned with the richest tapestry. Tables of ivory and cedar-wood were placed before them, and on these their viands were presented in vessels of gold and silver. They danced to the sound of "flutes and soft recorders," or moved about the theatre in measured and harmonious steps, scattering around them the freshest and the choicest flowers. Arrian mentions an elephant which played on symbols, one being fastened to each knee, and another held by his proboscis, while his unwieldy companions danced in a circle, keeping time with the greatest exactness.

The general use of gunpowder in the practice of war, and the application of steam to machinery, have greatly superseded the employment of this gigantic living engine for the purposes of the human race, although it is still extensively used as a beast of burden in the East. In regard to the pecuniary value of the elephant, Mr Forbes informs us that a common price is from 5000 to 6000 rupees, but that he has seen one valued at 20,000.[1] We must now terminate our miscellaneous notices of this interesting genus.[2]

FAMILY II.—PACHYDERMATA PROPER.

In the majority of this family the three sorts of teeth exist together, and the number of toes ranges from two to four. Those in which the toes are of an even number have their feet in a measure cloven, and approach the ruminants both in the structure of the skeleton, and the complicated form of the stomach.

GENUS HIPPOPOTAMUS, Linn. Incisives $\frac{4}{4}$, canines $\frac{1-1}{1-1}$, molars $\frac{6-6}{6-6}$; $= 36$.[3] Body very bulky, legs proportionally short, the feet with four toes terminated by small hoofs. Lower incisives cylindrical, and directed obliquely forwards. Skin extremely thick, and hairless.

Only one species of this genus is distinctly known to naturalists, the *Hippopotamus amphibius* of systematic writers.[4] Next to the elephant and rhinoceros this is probably the most bulky land animal with which we are acquainted. It is peculiar to Africa, where it inhabits the fresh waters of the central and southern portions of that sultry continent. It appears to have formerly existed in Lower Egypt, but has long since disappeared from that district. It is, however, well known in Abyssinia. Mr Salt had no sooner reached the banks of the Tacazze, a tributary of the Nile, than his attention was roused by the cry of his attendants of "Gomari! Gomari!" the native title of the hippopotamus; but he at that time succeeded in obtaining only a momentary glance, which sufficed to shew that its action somewhat resembled the rolling of a grampus in the sea. The river was about fifty yards across, and between its fords, at the place alluded to, there are pools of almost immeasurable depth, resembling the wild and beautiful mountain tarns of the north of England, and in these the amphibious giants love to dwell. Mr Salt and his party stationed themselves on a high overhanging rock which commanded a deep translucent pool, and they did not remain long before a hippopotamus rose to the surface at a distance of twenty yards. He came up very confidently, raising his enormous head above the water with a violent snort. The muskets were instantly discharged, their contents seemed to strike directly on the forehead, on which he turned round his head with an angry scowl, and making a sudden plunge, descended to the bottom, with a peculiar noise between a grunt and a roar. The sportsmen for a time entertained the hope that he was killed, but he ere long rose again close to the same spot, apparently not much concerned at what had happened, but with somewhat greater caution than before. The guns were again discharged, but as ineffectually as before; and although some of the party continued firing at every one that made his appearance, they were by no means certain that the slightest impression was produced. This they attributed to their having used *leaden* balls, which are too soft for such almost impenetrable skulls. One of the most interesting parts of the amusement consisted in witnessing the perfect ease with which these huge creatures quietly descended to the bottom, for the water being exceedingly clear, they were distinctly perceptible at least twenty feet beneath the surface. They are able to remain five or six minutes at a time under the water.[5] The flesh of the hippopotamus is used as food by many of the African tribes; its skin is also employed for a variety of purposes, and its teeth yield an ivory of great value.

---

[1] *Oriental Memoirs.*

[2] In addition to the works already quoted, we have in this as in some other parts of our present treatise, availed ourselves of the natural history sketches contained in various volumes of the *Edinburgh Cabinet Library.*

[3] An additional molar is sometimes found on each side of the upper jaw, but it seems of a temporary nature.

[4] M. Desmoulins regards the species of Senegal as distinct from that of the southern extremity of Africa.

[5] Salt's *Voyage to Abyssinia*, p. 345.

Genus Sus, Linn. Incisives $\frac{4}{6}$ or $\frac{6}{6}$, canines, $\frac{1-1}{1-1}$, molars, $\frac{7-7}{7-7}$; $= 42$ or 44. All the feet furnished with four toes, of which two are anterior or intermediate, and of larger size, and two are lateral or posterior, and so short as scarcely to touch the ground. The lower incisives always project forwards, and the canine teeth, even those of the upper jaw, likewise project and curve upwards. The snout is lengthened, and truncated at the point.

The wild boar (*Sus aper*), the supposed origin of our domestic breeds of swine, occurs in many parts of Europe, Asia, Africa, and the islands of the Indian Sea. Its body is of a brownish-black colour, covered with bristles, which are hard and stiff, especially along the spine. It is an animal of great strength, and considerable activity; but its dimensions though large, probably never exceed those of an overgrown individual of the domestic breed. Wherever the boar occurs in a state of nature, he is found in moist and shady situations, generally well wooded, and for the most part not far distant from streams and marshes. He prefers even cultivated grounds, with all the dangerous consequences likely to result from such localities, to dry or open tracts of weather-beaten barrenness. However fierce in self-defence, when attacked in some favourite place of strength, or irritated during the rutting season, when his passions are inflamed, his natural tastes are almost entirely herbivorous. Buffon, however, states that they have been seen eating horse flesh; and the skin of deer, and the claws of birds, have been sometimes found within them. Desmarest asserts that they devour the smaller kinds of game, such as leverets and partridges, and are very fond of eggs. Their habits are rather nocturnal, at least they are frequently observed to quit their coverts during the evening twilight, and when they hold their lair in the vicinity of human cultivation, they often do great damage by turning up the soil in long straight deep furrows, in search of roots or grain. By means of their delicate perception of the sense of touch and smell, they discover and disinter many low growing plants, half sunk beneath the soil, and hence probably their desire to dwell in moist and sombre places where, amid "a boundless contiguity of shade," their natural powers are more easily and efficiently exerted. They continue to increase in size and strength for four or five years, and are said to live for about thirty years. It is when they have nearly attained maturity, that they afford the most exciting and dangerous occupation to the sportsman. A strong boar will then continue to run for a long time, and finally make the most vigorous and determined self-defence. An experienced boar exhibits considerable intelligence in avoiding his enemies, although the strong scent which emanates from him, especially in a state of irritation, renders his eventual escape from the dogs extremely doubtful. In his revenge also, there is said to be less of blind and indiscriminate fury than might be expected from his coarsely savage aspect; for even when harassed beyond the hope of life, and about to be torn to pieces by the insatiate hounds, should he receive a ball from the huntsman's rifle, he has been known to turn upon his dread pursuers, to break through the bellowing pack, and to single out and assault with savage ire his human persecutor.[1]

The wild boar is among the fiercest of the animals of India. It there inhabits chiefly the woods and jungles; but when the grain is nearly ripe, it occasions great damage in corn fields, and still greater among sugar plantations. In eastern countries it is spread over a vast extent of territory, and exists in great abundance in the Archipelago of the Papuas, to the north of the Moluccas, and the westward of New Guinea. It would even appear that there are two wild species in the Celebes (besides *Sus Babyrussa*), and some writers are of opinion that there exists in the Indian and Chinese dominions a species distinct from the wild boar of Europe, and the more probable source from which the Siamese breed, and that of China, have been derived.

We cannot here enter into a detailed history of our numerous cultivated breeds. With a repulsive aspect, an ungraceful form, the most sensual habits, and a ferocity of disposition not seldom approaching to that of the carnivorous tribes, the domestic hog is nevertheless one of the most useful of quadrupeds. If the value of a benefit depends in a great measure on its universality, this despised animal may indeed claim a higher rank than many of a loftier nature; for one of the most singular circumstances in its history is the immense extent of its distribution, more specially in far removed and isolated spots, inhabited by semi-barbarian people, to whom the wild species is utterly unknown. The South Sea Islands, for example, on their discovery by Europeans, were found to be well stocked with a small, black, short-legged hog; and the traditionary belief of the human natives, bore that they were as anciently descended as themselves. The hog, in fact, is in these islands the principal quadruped, and is of all others the most carefully cultivated. The bread-fruit tree, either in form of a sour paste, or in its natural condition, constitutes its favourite food, and its additional choice of yams, eddoes, and other nutritive vegetables, rendersits flesh most juicy and delicious,—its fat, though rich, being at the same time (so says Foster) not less delicate and agreeable than the finest butter. Before our missionary labours had proved so signally successful in those once forlorn and benighted regions, by substituting the mild spirit of Christianity for the sanguinary forms of a delusive and degrading worship, the Otaheitans, and other South Sea islanders, were in the habit of presenting roasted pigs at the *morais*, as the most savoury and acceptible offering to their deities which they could bestow. Hogs are now abundant in America. They were not, however, indigenous to the New World, but were transported thither by the Spaniards, soon after the discovery and conquest by that nation of the western regions. China is famous for its pigs, and throughout most of the provinces is much more abundant than mutton. Indeed the powerful and prevailing love of the former viand has even been assigned by a philosophical historian as a principal reason for the rejection by the subjects of the celestial empire, of the laws and religion of Mahomet.[2]

Of animals allied to the boar we may name the *Sus larvatus*, a species which occurs in Madagascar and Southern Africa, and the *Sus Babyrussa* (see Plate XI., figure 4), a native of the Indian Archipelago, distinguished by its longer and more slender limbs, and the extraordinary length of its upturned and greatly curved tusks. The genus **Phacochœrus**, F. Cuvier, has only two incisives in the upper jaw, and even these are often wanting, though their vestiges are sometimes found beneath the gums. It is also characterized by a large and fleshy lobe on either cheek. The species (supposed to be two in number, if that described by Ruppel is really distinct) are fierce and savage animals, which, when attacked, become extremely furious, and rushing on their enemies with great force and swiftness, occasionally inflict the most desperate and sometimes fatal wounds. The genus **Dycoteles** of Cuvier, has four incisives above, six below, with two canines and six molars in each jaw. The species differ from all the preceding porcine groups in the canines being directed in the ordinary

[2] Ibid. vol. ii. p. 877.

Pachydermata.

Pachydermata.

manner, in there being only three toes to the hinder feet, and in the tail being tubercular. These animals, commonly called *peccaries*, are native to South America, where there are two species, the collared peccary (*D. torquatus*), and the white-lipped peccary (*D. labiatus*). The former inhabits the Atlantic coasts of the New World from Guyana to Paraguay, the latter occurs in parts of the same extensive range, and is sometimes met with in vast flocks. It is easily tamed, and its flesh is good to eat. Prior to the practical researches of Azara, both species seem to have been confounded under the title of *Sus Tajassu*, Linn.

GENUS RHINOCEROS, Linn. The number of teeth in this genus differs according to the species. Each foot is divided into three toes. The bones of the nose, which are very thick, and united into a hollow arch, bear one or more horns, which adhere to the skin, and are composed of a fibrous substance, resembling a mass of agglutinated hairs.

The species, of which four or five are known to naturalists, are of a dull and heavy aspect, and of much more restricted capacity than the elephant. Though inferior also in size to that sagacious creature, they are yet of sufficiently gigantic dimensions to form a very imposing feature in zoology. Their senses of sight and touch are said to be rather defective; those of smell and hearing more acute. A young rhinoceros, kept in the Garden of Plants, in Paris, was habitually gentle, obedient to his keepers, and extremely sensible of kindness. He exhibited, however, at times the most violent paroxysms of rage, during which it was necessary to keep beyond " the pale of such contention," as it would have been but poor comfort to those whom he might have gored, to be informed that his ordinary proceedings were entirely innocuous. He was usually mitigated by a liberal supply of bread and fruit, and as soon as he saw those who were in the habit of feeding him, he would stretch his muzzle towards them, open his mouth, and extend his tongue.

The preceding observations apply to the species of continental India (*Rhinoceros Indicus*, Cuv., see Plate XI., fig. 8), which, besides twenty-eight molars, has two strong incisive teeth in each jaw, two others of a smaller size between the lower incisives, and one still smaller on each incisor of the upper jaw. It has only one horn, and its skin forms deep folds behind and across the shoulders, and before and across the thighs. " The power of this species is frequently displayed to a surprising degree when hunting it. A few years ago, a party of Europeans, with their native attendants and elephants, when out on the dangerous sport of hunting these animals, met with a herd of seven of them, led, as it appeared, by one larger and stronger than the rest. When the large rhinoceros charged the hunters, the leading elephants, instead of using their tusks or weapons, which, in ordinary cases, they are ready enough to do, wheeled round, and received the blow of the rhinoceros on the posteriors. The blow brought them immediately to the ground with their riders, and as soon as they had risen, the brute was again ready, and again brought them down, and in this manner did the combat continue until four of the seven were killed, when the rest made good their retreat.[1]

The rhinoceros of Java (*Rh. Javanus*, Cuv.) is possessed of the large incisives and single horn of the Indian species, but its skin has fewer folds, and is entirely covered with small close-set angular tubercles. A third eastern species occurs in Sumatra (*Rh. Sondaicus*, Cuv.). Its skin is more hairy, with scarcely any folds, and there is a small horn behind the ordinary one.[2]

The African species have two horns, no folds on the skin, and want the incisive teeth. The best known is the *Rhinoceros Africanus* of modern writers,—*Rh. bicornis*, Linn. Its name was changed on the discovery of the two-horned Sumatran species, and the title of *African* was bestowed upon it, in the erroneous belief that it was the only species found upon that continent. But the discovery of a distinct species in the interior of southern Africa by Mr Burchell (and which that traveller names *Rh. simus*), affords a proof, among many others which might be adduced, of the impropriety of naming any species from the continent which it inhabits. Few creatures stand so " alone in their glory" as to exist over a vast tract of country without claiming kindred with any other, and it may almost be inferred *a priori* that when one of a genus is discovered, a second or a third will ere long be ascertained. When this happens, such names as *Africanus*, *Americanus*, &c. cease to be discriminating, and consequently lose their value. In the mean time, we have no means of ascertaining the difference in the geographical distribution of the two species of African rhinoceros, or how far their history and description may not have been confounded by travellers. Mr Burchell's species is chiefly distinguished by the truncated form of the lips and nose, and by its general dimensions being much larger. It was first met with amid immense plains near the 26° of south latitude, and was described by the natives as feeding on nothing but grass, while the other is said to browse on shrubs and branches. One or other of the species extends over a great expanse of Africa, where they are much esteemed as food, the tongue especially being regarded as a great delicacy. The hunters of the rhinoceros are called *agageer* in Abyssinia, from agaro to kill, by cutting the hams or tendon of Achilles, with a sword. The eyes of the animal being extremely small, his neck stiff, and his head very ponderous,[3] he seldom turns round so as to see any thing that is not directly before him. To this, according to Bruce, he owes his death, as he never escapes if there is as much plain ground as to enable a horse to get in advance, for his pride and fury then induce him to lay aside all thoughts of escaping but by the victorious overthrow of his enemy. He stands for a moment at bay, then starting forward, he suddenly charges the horse, after the manner of a wild boar,—an animal which he greatly resembles in his general mode of action. The horse, however, easily avoids this heavy though impetuous onset, by turning short aside,—and now is the fatal instant,—for a naked warrior, armed with a ruthless sword, drops from behind the principal hunter, and, unperceived by the huge rhinoceros, who seeks only to wreak his vengeance on his more open enemy, he smites him with a tremendous blow across the tendon of the heel, and thus renders him incapable of further flight. It may be easily conceived that his rage is great, and his resistance vain.

A rhinoceros in confinement will consume towards two hundred pounds of vegetable substances in a day. They are usually fed on moistened beans, hay, carrots, and a certain allowance of grain. In speaking of the supply of vegetable matter essential to the support of so gigantic a living mass, we must likewise bear in mind the vast quantity of water which it consumes. No country, according to Bruce, but such as that of the Shangalla, deluged with six months' rain, full of large and deep basins hewn by nature in the living rock, and shaded from evaporation by dark umbrageous woods, or one watered by extensive and never-failing rivers, can supply the enormous draughts of his capacious maw.[4]

[1] Griffiths's *Animal Kingdom*, vol. iii. p. 426.

[2] For a description of its habits of life, see Dr Horsfield's *Zoological Researches in Java*.

[3] A head, when disjoined from the vertebræ, is described by Mr Burchell as being of such enormous weight that four men could merely raise it from the ground, and eight were required to place it on a carriage.

[4] We may here note an opinion entertained both by Mr Salt and Baron Cuvier, that the figure of the African rhinoceros given

We shall here briefly notice the Genus HYRAX of Hermann, which seems to contain only a single well authenticated species (*H. capensis* and *syriacus*, figured in Plate XI., fig. 5), described under a variety of names, such as daman, Cape marmot, Cape çavy, &c. It is an animal of the dimensions of a rabbit, with a greyish-coloured fur. It was long classed among the Rodentia, probably on account of the smallness of its size; but, as Cuvier has remarked, with the exception of the horn, which is here wanting, the hyrax may be said to represent the rhinoceros in miniature. It has exactly the same molars, but there are two strong incisives curved downwards in the upper jaw, and, in the young state, a pair of small canines; there are four incisives in the lower jaw. The fore feet have four toes, the hinder three, all furnished with very small rounded hoofs (or rather nails, for in this respect our present genus seems to form an exception to its order), except the inner toe of the hinder extremities, which bears a curved oblique nail. The tail is tubercular. This animal has twenty-one pair of ribs, being exceeded in that number, we believe, by only a single quadruped, the *unau* or two-toed sloth, which has twenty-three. In this character, as in many others, it agrees with the pachydermous tribes in general, all of which have numerous ribs; whereas the majority of the Rodentia have only twelve or thirteen pair of ribs, those of the beaver alone amounting to fifteen. The hyrax is spread over a vast portion of Africa from the Cape of Good Hope to the north of Abyssinia. It dwells in clefts of the rocks, feeding on herbs and roots. Bruce describes it as "found in Ethiopia, in the caverns of the rocks, or under the great stones in the Mountains of the Sun, behind the queen's palace at Koscam. It is also frequent in the deep caverns in the rock in many other parts of Abyssinia." It is there called *ashkoko*, and several dozens are frequently seen sitting together upon great stones at the mouths of caves, enjoying the warmth of the mid-day sun, or the freshness of a fine summer evening. They are gentle and easily tamed, though at first, if roughly handled, they are apt to bite. "In Arabia and Syria he is called Israel's sheep or gannim Israel, for what reason I know not, unless it is chiefly from his frequenting the rocks of Horeb and Sinai, where the children of Israel made their forty years' peregrination; perhaps this name obtains only among the Arabians. I apprehend he is known by that of saphan in the Hebrew, and is the animal commonly called by our translators cuniculus, the rabbit or coney."[1]

GENUS TAPIR, Linn. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{7-7}{7-7}$; $=44$. Muzzle prolonged into a small fleshy trunk, but not prehensile. Anterior feet with four toes, posterior with three. Tail very short.

The most anciently known of this genus is the *Tapir Americanus*, supposed to be the largest quadruped native to the southern division of the New World, where it is very generally distributed from the Isthmus of Panama to the neighbourhood of the Straits of Magellan, being, however, more abundant in Guyana than in Paraguay. Its prevailing colour is deep brown, and there is a small mane on the upper portion of the neck of the male. This species measures nearly six feet in length, with a height of about three feet six inches. It is hunted by means of dogs, on account both of its flesh and hide, the former being held in some esteem by the Indians, whose taste is not distinguished for delicacy. When pursued, it seeks its safety by bursting through close and thorny thickets, where it is with difficulty followed by its thinner skinned enemies. It is also sometimes shot by those who lie in ambush during the night among the water melons, its accustomed food. It is tenacious of life, if we may judge from the account given by Azara, who saw one run for some time after it had received two balls through the heart. It is a solitary animal, of nocturnal habits, easily tamed if taken young. See its cranium on Plate XI., figure 6.

A second American species has been discovered of late years by M. Roulin,[2] and described under the title of *Tapirus pinchaque*. It is nearly equal in size to the preceding, and resembles it in its general form and aspect, but its osteological structure exhibits a considerable difference, and it is said to occur only at a great height among the mountains.

The only other described species is the Malay tapir of Raffles and Horsfield (*Tapir indicus*, Cuv., Plate XI., figure 7). It is a native of Sumatra and the Peninsula of Malacca. It exceeds the American kinds in size, and is further distinguished by a peculiar and contrasted colouring, the head, shoulders, and fore and hind legs being of a blackish-brown, while the intermediate portion of the body is of a dingy white. Though a common animal in the east, its habits in a state of nature are but little known. The specimen described by Sir T. S. Raffles was young and tractable. It roamed about the park at Barrackpore, and was frequently observed to enter a pond and walk along the bottom under water, but without any exercise of the ordinary mode of swimming.[3]

FAMILY III.—SOLIDUNGULA.

We here place the different species of the horse tribe, technically characterized by possessing only one external toe to each foot, covered by a single undivided hoof. But, beneath the skin on each side of the metacarpal and metatarsal bones, are two small protuberances or styles, which represent the lateral toes. The three kinds of teeth exist in the males; the canines are almost always wanting in the females.

GENUS EQUUS, Linn. Incisives $\frac{6}{6}$, canines $\frac{1-1}{1-1}$, molars $\frac{6-6}{6-6}$; $=40$. Upper lip developed and flexible. Eyes lateral. Ears large, pointed, moveable. Limbs long and slender. Tail of medium length, and either furnished throughout its whole extent with long hair, or terminated by a somewhat lengthened tuft. Stomach simple, and of medium size; intestines very long; cœcum enormous.

According to the views of modern naturalists, this important genus consists of six distinct, though nearly allied species, namely, the horse (*Equus caballus*), the dziggithai (*E. hemionus*), the ass (*E. asinus*), the quagga (*E. quagga*), the zebra or mountain zebra (*E. zebra*), and the zebra of the plains (*E. Burchellii*). It has been remarked that the characters which distinguish these animals from each other, though sufficient for the purposes of the naturalist, are not, anatomically considered, of an essential nature. They are rather superficial, consisting chiefly in the comparative size of the ears, the length and texture of the hair, and the distribution of the external colours. As the size varies remarkably in several of the species, the difference of dimension can scarcely be assumed as a specific character. Hence the most accomplished comparative anatomist can with difficulty distinguish a species merely from the inspection of a few isolated bones, although such inspection is amply suffi-

---

by Bruce must have been copied, for convenience, from the one-horned species of Buffon, with the addition of a second horn, as the two-horned rhinoceros wants the folds in the skin, which are nevertheless represented by the Abyssinian traveller.

cient for the determination of species in the case of almost all other groups of which we possess an osteological knowledge. We shall devote a few sentences to each of the animals above enumerated.

Equus caballus. The Horse. Our cultivated breeds of this invaluable creature are now so numerous, that a volume would scarcely suffice for their record. We shall here confine ourselves to the few facts within our knowledge which illustrate its *natural* history, properly so called,—for one great effort of the zoologist should consist in the distinguishing of facts which depend on instinct, and are therefore natural to an animal, from those which result artificially from education and an altered mode of life,—in ascertaining what really appertains to it as a natural inheritance, as well as what it may have derived through the intervention of man,—and in avoiding to confound "the animal with the slave, the beast of burden with the creature of God."[1] In the present case, however, it must be admitted, that the domestic breeds are improved not more in usefulness than in beauty and grandeur of aspect, whatever poets may fancy to the contrary in a wild horse of the Tartarian deserts. The following are the characters which distinguish this animal in a state of nature. The head is large in proportion to the body; the front, above the eyes, bulging or convex; the forehead straight; the ears long, carried habitually low, and pointing backwards, thus producing a somewhat vicious aspect; the circumference of the mouth and nostrils is garnished with long hairs; the mane is very thick, and prolonged beyond the withers; the back is less vaulted than in the domestic varieties; the legs are proportionally longer and thicker; the hair, sometimes long and waving, is never smooth; its colour, usually dun or brown, sometimes varies to a kind of cream-colour, but is never either black or pied. These are the characters of the *tarpan* or wild horse of the Tartarian deserts; and similar features seem to have been reproduced in the Spanish or Andalusian race, now wild in the pampas of the New World to the south of Buenos Ayres. There the size has decreased, the limbs become thicker, the neck and ears longer, and the varied colouring has, in a great measure, disappeared,—there being usually about ninety chestnut bays in the hundred, while black is so rare that there is scarcely one out of two thousand of that colour. Now, as all emancipated animals exhibit a tendency to recover after a certain lapse of time, and as a consequence of liberty, not merely the manners and instinctive inclinations, but also the form and colour of their primitive types, M. Azara concludes that this chestnut bay is the original hue of the horse. According to Foster there are neither pied nor black horses among the wild troops of central Asia, among which the dun and greyish-brown prevail, and one or other of these is therefore by some regarded as the natural colour. The hair of the South American troops has scarcely increased in length; but this is probably owing to the greater mildness and equality of temperature which prevail in their adopted country, than in the climate of the north of Asia. One remarkable distinction, however, is said to exist between the disposition or temper of the South American and Asiatic wild horses. It is this. At whatever age the former are caught, they may be rendered, in a measure, fit for the service of man almost in a few days, whereas the latter can only be tamed when taken young, and frequently shew themselves in after life to have been but half subdued. Does not this go far to prove that the one is the genuine original,—the other but a rebel race?

The native country of the horse is believed to be those desert regions which environ Lake Aral and the Caspian Sea. Although no doubt exists as to the occurrence of wild, or at least of what may be called independent horses in those countries, as well as in the southern parts of Siberia, in the great Mongolian deserts, and among the *kalkas*, to the northwest of China; yet it ought not to be concealed that some thoughtful inquirers are of opinion that these also, as well as those of America just mentioned, are merely emancipated tribes, descended at some remote period from an enslaved stock, and that the real wild horse, using the expression as we apply it to other animals existing entirely (and *ab initio*) in a state of nature, is extinct. The wild horses, for example, mentioned by Pallas as pasturing in the deserts on each side of the river Don, in the vicinity of the Palus Mæotis, are now believed, if not ascertained, to be the offspring of the Russian horses employed in the siege of Asoph in the year 1697, and which, for want of forage, were at that time intentionally turned adrift. Their descendants have now assumed an aspect of great natural wildness.

In Asia each congregated troop seldom exceeds twenty individuals; but, in America, many thousands are sometimes seen together. In both these distant regions a peculiar variety has sprung up with crisped or frizzled hair; but those of Asia are always white, while the American (frizzled) variety is of every colour except white and pied. When we consider the almost constant relation which may be traced between the length and abundance of hair, and an increased degree of cold, we might have expected to discover this frizzled variety of the New World rather towards the colder country of Patagonia, than in Paraguay, just as the corresponding variety of Asia is found beneath the varying climate of the Baskir nation. According to Azara those magnificent troops of *insurgent* horses (*Alzados* is the Spanish term) which have become wild in the plains of America, to the south of the Rio de la Plata, sometimes amount to 10,000 individuals. Preceded by videttes and detached skirmishers, they advance in a close column so broad and dense that nothing can break through it. If a travelling caravan, or a body of cavalry, is seen approaching, the leaders of the wild horses advance upon a reconnoisance, and then, in accordance with the movements of the chief, the entire body passes at a gallop to the left or right, inviting, at the same time, by a deep prolonged neighing, the domestic horses to desertion. These often join the "rebel host," and are said never voluntarily to submit themselves again to man's dominion. Each of these great squadrons is composed of a re-union of smaller companies, themselves consisting of as many mares as a single horse can keep under a loving subjection. Descended, as we have said, from the ancient breed of Andalusia, these animals are, however, inferior to their noble ancestry in beauty, strength, and swiftness. Their heads are thicker, their limbs coarser and less symmetrical, their necks and ears longer; and, in all these qualities, it has been remarked, they approach again to the supposed primitive model which still exists in a state of freedom, amid the illimitable wilds of the Tartarian deserts. Domestication, therefore, is not, as Buffon has so eloquently maintained, in all cases prejudicial to the nature of an animal; for the *beau ideal* of a horse is undoubtedly to be found, not among the desert tribes, as the French Pliny supposes, but rather in one of the cultivated races of Spanish or Arabian birth.[2]

Equus hemionus, Pallas. The Dziggithai. This species bears a considerable resemblance to a mule in size and figure, but is much more elegant. It is called *Hemionos* (literally half-ass) by Aristotle, and is mentioned by that philosopher as occurring in ancient times. It is of a greyish isabella colour. The coat, during winter, is tufted like that of a camel, but in summer it is scarcely three lines in length, and is distinguished by radiated marks like ears of corn, scattered here and there upon the flanks. The existence of this animal in Syria was known to ancient writers. Ælian describes it as a native of India. The first of the moderns by whom it was recognised appears to have been Messerschmidt; but it is to Pallas that we are indebted for its genuine history. It is confined at the present day to the *steppes* of Central Asia, and is found especially in the desert of Cobi. There is certainly no modern proof of its existence to the west of Lake Aral, and the mountains of Belur. It neither penetrates into forests, nor ascends mountains. Its neighing is more grave and sonorous than that of a horse; and it is described as bearing its head and neck loftily like a stag. It can travel fifty or sixty leagues across the desert without drinking, and its congregated bands do not consist of more than about twenty females and foals, under a single male chief. Sometimes several males are observed together, followed only by four or five females. The rutting season takes place towards the end of August, and the young are produced in spring. There is usually only one brought forth at a time, which attains the adult state in three years. The chase of this animal affords a favourite pastime both to the Monguls and Tanguts; but its prodigious and proverbial swiftness, aided by a piercing sight, and an acute sense of smell, generally baffles the exertions of the most experienced and best mounted huntsmen.

---

[1] Buffon.

[2] For a detailed account of the domestic breeds see article HORSE in this Encyclopædia; also Culley's *Observations on Live Stock*, Marshall's *Economy of Yorkshire and the Midland Counties*, the works of Buffon, Bewick, &c.; and the volume entitled *The Horse*, in the farmer's series of the "Library of Useful Knowledge." Our own sketch of the genus *Equus* coincides with, and is indeed chiefly compiled from materials which we had sometime ago occasion to collect from various sources for the formation of an essay "On the Origin and Natural History of the Horse and its allied Species," published in the Edinburgh *Journal of Agriculture*, No. vii.

Equus asinus. The Ass. As in our preceding notice of the nobler horse we dwelt chiefly upon its natural attributes, so in this humble species we may distinguish between the indigenous and subdued kinds. The Onager, or wild ass, called *koulan* by many of the tribes of Asia, differs from the domestic breed in its shorter ears, the greater length and finer form of its limbs, its straighter chest, and more compressed body. In its general aspect, it is said to resemble a young foal. The males alone are characterized by the transverse bar across the shoulders, observable in the domestic ass, and, in the wild species, it is sometimes double. The onager was well known to the ancients, although it appears to have been lost sight of during the dark ages, and to have been but obscurely known for several centuries after the revival of learning. Indeed we possessed no good modern elucidation of its history till the time of Pallas.[1] The Turkish name of this animal, *Dagh aischaki*, or mountain ass, points out its natural locality, elsewhere beautifully indicated,—"Whose house I have made the wilderness, and the barren land his dwelling. The range of the mountains is his pasture, and he seeketh after every green thing."[2] Even the choice which the domestic ass may be often seen to make of the narrow and uneven paths by the wayside, is probably a remnant of this natural instinct. The native country of the wild ass is the same as that of the horse; but, while the latter extends as far north as the 56°, the former does not voluntarily pass beyond the 45°. In its southern migrations, however, it descends to the Persian Gulf, and even towards the southern extremity of Hindostan. It was seen by Odoar Barboza among the mountains of Golconda; and those troops of wild horses mentioned by Turner as frequenting the upland countries of Boutan, where they are called *Gourkhaws*, were, in fact, onagers or wild asses. Eye-witnesses have also assured Pallas of their having frequently observed in the Tartarian deserts, and those of Persia, the route of congregated wild asses, forming a path of 300 toises (above 600 yards) broad. The food of the wild ass, according to Dr Shaw, consists chiefly of saline, or bitter and lactescent plants. It is also fond of salt or brackish water. Its flesh is highly esteemed by several oriental nations, and its skin is known in commerce under the name of chagrin, so called from the Turkish term *sagri*. The engrained aspect which it bears is not, however, natural to it, but is produced by a chemical process described by Pallas. In regard to the domestic ass, its manners and appearance, as it exists in this country, are so familiar as to render description needless. The races of eastern origin are much more beautiful, with glossy skins, carrying their heads loftily, and moving their limbs in a very graceful manner. They accordingly fetch a high price. Some contrariety of opinion exists regarding the progress of their introduction westward, and their great uniformity of aspect, compared with the multiplied varieties of the horse, has induced some to suppose that asses have not been so long nor so generally under the dominion of the human race. In the time of Aristotle they were not found in Thrace, nor even in Gaul; but, on the other hand, we know, from the sacred writings, that they were used as beasts of burden in the remotest ages of the Jewish history, and were, therefore, in all probability reduced to servitude by the eastern nations fully more early than any other animal not essential to the existence of a pastoral people. Buffon is of opinion that the domesticated breed of asses used in Europe came originally from Arabia; that they first passed into Egypt, and thence to Greece, Italy, France, Germany, England, &c. Those used in more northern countries have been introduced at a comparatively recent period. Indeed, even in England, according to Hollinshed, so late as the days of Elizabeth, "our lande did yeelde no asses." If it were so, they must have become extinct, for there is no doubt of their existence in this country during a period long prior to the golden days of "good Queen Bess." They are mentioned in the reign of Athelred, and again in the time of Henry III. They may, however, have been reintroduced to Britain in the time of Elizabeth's successor, upon the renewal of our intercourse with Spain, a country famous for the production of both ass and mule. "The relation of Lucilius," says Sir Thomas Browne, "now become common concerning Crassus, the grandfather of Marcus, the wealthy Roman, that he never laughed but once in all his life, and that was at an ass eating thistles, is something strange. For, if an indifferent and unridiculous object could draw his habitual austereness into a smile, it will be hard to believe he could with perpetuity resist the proper motion thereof."[3]

Equus quagga. The Quagga. This animal measures about four feet in height at the withers. The head and neck are deep blackish-brown, striped with greyish-white lines, transverse upon the cheeks, but longitudinal on the temples and forehead, and forming triangles between the mouth and eyes; the other parts are of a clearer brown, paler beneath, and almost white upon the belly. The mane is blackish, and resembles that of a horse which has been *dressed.* A black line runs along the spine to the tail. The quagga inhabits the karoos or flats of southern Africa, and frequently pastures in company with the zebra, of which it was for a long time regarded as the female. The existence of two so nearly allied species within the same geographical boundaries, and subject to constant association, without any third or intermediate variety having sprung up, may be regarded as a proof that animals of distinct kinds, in a state of freedom, have no sexual intercourse with each other; while the entire similarity, or rather identity of climatic influences, under which these two species co-exist, also demonstrates that neither is derived from the other, but that each has descended from a separate type, and forms a primitive species. The quagga is of a much more docile and pliant disposition than the zebra, and is consequently more easily rendered subservient to domestic uses. A curricle drawn by a pair of these animals has been often seen during the gay season in Hyde Park. The late Lord Morton succeeded in raising mules between the quagga and mare, and, in the course of his experiments, a rather singular circumstance occurred. The mare which had produced the hybrid or mule, gave birth several seasons afterwards to a foal which exhibited decidedly the markings of the quagga coat, although the mother had not, in the mean time, associated except with her natural mate, the horse. Indeed her former friend, the quagga, had been dead for more than a year.

[3] *Pseudodoxia Epidemica.*

Equus zebra, Linn. *E. montanus*, Burchell. The Zebra, or mountain zebra. This species resembles the mule in shape. Its head is rather large, its ears long, it limbs elegantly small, its body well formed, round, and fleshy. But its most remarkable character consists in the extraordinary regularity of its stripes, or markings of alternate colours, which seem rather an effect of art than the genuine production of nature. The head is striped with delicate bands of black and white, which form a centre in the forehead; the neck is adorned with stripes of the same colour running round it; the body is beautifully variegated with bands running across the back, and ending in points at the belly; and its thighs, legs, ears, and tail, are all beautifully streaked in the same manner.[1] The sexes nearly resemble each other. In the young the dark coloured bands of black or brown are paler. The female carries for twelve months. She has been known to breed in confinement with both the horse and ass. M. F. Cuvier has figured and described a mule produced between a female zebra and a Spanish ass. (See Plate XII., figure 2.) It sucked for a year, and was at first of a peaceable nature, but as it increased in size it lost its resemblance to its mother, and also became very stubborn and mischievous.[2] Its coat, when we last heard of it, was of a deep grey, varied on the withers, legs, and tail, by transverse bands. It never neighed, loved to roll itself on the moist ground, attacked all and sundry both with hoofs and teeth, and was indeed a most unamiable creature. The inhabitants of the Cape have never succeeded in their attempts to reduce the zebra to subjection, although Sparmann records an instance of a rich citizen who, to a certain extent, had managed to subdue them. On attempting, however, on one occasion to yoke them to his chariot, he nearly forfeited his life, for, without warning, they rushed back to their stalls, with every symptom of fury and indignation. Buffon was misinformed when he reported a statement (corrected in one of his supplementary volumes), that zebras were used in Holland. Mr Barrow, however, seems to think, that if judicious means were perseveringly made use of, these gay and fantastic creatures might still be reduced to an available servitude, notwithstanding their naturally wild and vicious disposition; and M. F. Cuvier mentions an instance of a zebra which was so tame as to suffer itself to be handled and mounted without difficulty. This species was known to the ancients under the name of *hippotiger*, a term by which it is well designated, as possessing the form of a horse, with the striped hide of the great feline destroyer.[3]

Equus Burchellii, Gray. *Equus zebra*, Burchell. The Zebra of the plains. Although our knowledge of this beautiful animal is originally due to Mr Burchell, who was the first to perceive that South Africa produced two species (besides the quagga), we seem to owe the more precise settlement of its distinctive characters to Mr W. E. Gray. It appears, in fact, that the traveller above named, after ascertaining that there really were two different kinds of this animal, fell into the error of describing the one previously known as the new species, while he overlooked, or did not sufficiently illustrate, the specific distinctions of the zebra of the plains, regarding it as the kind already well known, although it had, in reality, hitherto escaped the notice of naturalists. "The hoofs of animals," Mr Burchell observes, "destined by nature to inhabit rocky mountains, are, as far as I have observed, of a form very different from those intended for sandy plains; and this form is in itself sufficient to point out the dauw[4] as a separate species. The stripes of the skin will answer that purpose equally well, and shew, at the same time, the great affinity and specific distinction of the ass, which may be characterized by a single stripe across the shoulders. The quagga has many similar marks on the hind and fore part of the body; the zebra is covered with stripes over the head and whole of the body, but the legs are white; and *the wild paarde is striped over every part, even down to the feet*. The zebra and wild paarde may be further distinguished from each other, by the stripes of the former being double; that is, having a paler stripe within it, while the latter, which may be termed *Equus montanus*, is most regularly and beautifully covered with single black and white stripes: added to this, the former is never to be found on the mountains, nor the latter on the plains."[5] It is evident from the preceding descriptions (especially from the line which we have marked in Italics, and which applies exclusively to the old species), and from the comparison instituted by Mr Burchell himself, that although he is entitled to the merit of discovering that there were two distinct kinds, he has applied his new name to the old species, and confounded the new species under an old name. It therefore became imperative that his designations should be changed, because the well known zebra is, in fact, the *mountain horse*, and Mr Burchell's new species is the zebra of the plains. Hence the propriety of the emendations suggested by Mr Gray, who retains the name of zebra, as applying specifically to the animal so called by Linnæus and Buffon; and applies the epithet *Burchellii* to the other species, in deserved honour of the enterprising and intelligent traveller by whom it was discovered.[6] The student will not fail to perceive that the term *montanus*, though retained by Baron Cuvier[7] to distinguish the new species, is inapplicable to an animal which its first describer informs us "is never to be found on the mountains," and which was, in truth, originally applied by inadvertence to another species. We here exhibit a portraiture of the young of Burchell's zebra. (See Plate XII., figure 1.)

ORDER VII.—PECORA; RUMINATING ANIMALS.

This order is deemed by Baron Cuvier to be the most natural and best determined of the class of quadrupeds, as all the species seem constructed on the same model, although the camels present some slight exceptions to the prevailing characters. At all events, it includes species of the highest and most essential value to the human race. The characters of the order are somewhat negative. There are seldom any incisive teeth in the upper jaw, and those of the lower are usually eight in number. Between the incisive teeth and the molars there is an empty space, in which, in certain genera, are implanted the canines. The molars, almost always six on each side of both jaws, have their crowns marked by two double crosses, of which the convexity is turned inwards in the upper, and outwards in the lower teeth. The four limbs are terminated by two toes (hence the title of Bisulca, bestowed by Illiger), each covered by a hoof, and behind these hoofs there are sometimes two small spur-like projections,—the vestiges of lateral toes. The two bones of the metacarpus and metatarsus are united into one, commonly named the *canon* bone; but in certain species the vestiges of lateral bones are observable.

[7] *Règne Animal*, t. i. p. 253.

The most singular functional character in the natural economy of the tribes of our present order, consists of that *ruminating* faculty from which they derive their most familiar appellation. They possess the power of re-chewing their aliments, by bringing back the food for a second time into the mouth after it has been swallowed; and this power results from the peculiar structure of the stomach, which is in a measure quadruple,—the first three being so disposed in relation to the œsophagus, as to admit of either of them receiving the food. The first and largest is the paunch, which receives the mass of vegetable matter grossly bruised by a first and hasty mastication. It then proceeds into the second called the bonnet, the sides of which have laminæ resembling the combs of the honey-bee. This stomach is small and globular; it soaks the herbage, and compresses it into little pellets, which successively remount to the mouth, to undergo a second mastication. During this process the creature remains quiescent, "bedward ruminating," until all the food previously taken into the paunch has been subjected to it. When thus re-chewed, the aliments descend directly into the third stomach, and from thence into the fourth, the sides of which are plaited or wrinkled. This last is the true organ of digestion, and is analogous to the simple stomach of ordinary animals. As long as the young remain in the condition of sucklings, and are supported only upon milk, the fourth stomach is the largest of the whole, but, as soon as the herbivorous habit commences, and large supplies of bulky food become indispensable, the paunch acquires an enormous development. The intestinal canal is very long in all ruminants, but the larger intestines are but slightly pursed. The cæcum is likewise long and smooth. The fat of these animals hardens more in cooling than that of others, and even becomes brittle. The mammæ are placed between the hinder limbs.

With the exception of the horse and dog, all the most truly valuable species which have yet been subjected to the dominion of man, belong to the ruminating order; for example, sheep, rein-deer, camels, and "the cattle on a thousand hills." These either directly yield us the most important articles of human diet, or afford us the kindly protection of their woolly covering, or provide us with many indispensable articles from their strong tenacious hides; to say nothing of their uses as beasts of burden. They are all provided with antlers or horns, at least in the males,—with the exception of the two genera which contain the camels and musk deer, both of which are hornless. It may be as well to devote a few paragraphs in this place to a brief consideration of the nature of these important parts.

The organs of defence and attack with which the heads of ruminating herbivorous animals are furnished, are called, according to their structure and composition, either *antlers* or *horns*. With the former the stag, roe-buck, rein-deer, elk, are armed; antelopes, goats, sheep, bulls, are provided with the latter. Although both these kinds of defensive organs follow the same mode of formation, in so far as they are prolongations of the frontal bone, and have their materials supplied by bloodvessels, yet there exists between them a considerable distinction in relation to the different distribution of these vessels,—a distinction which occasions the periodical fall of antlers, and the permanence of horns. The bloodvessels of horns are internal, those of antlers external; the former are covered by a corneous substance, and increase from their bases, the latter are, for a time, invested by a prolongation of the skin, and, in growing, appear to sprout from their superior extremities.

Antlers, in their perfect state, according to Cuvier, are true bones, both in their texture and elements. Their external part is hard, compact, and fibrous; their internal spongy but solid. They have no large cells, no medullary cavity, and no sinuses. The bases of antlers adhere to, and form one body with the *os frontis*, in such a manner that at certain ages it is impossible, from their internal texture, to determine the limits between them; but the skin which covers the forehead does not extend further,—an irregularly toothed bony substance called the *burr* surrounding the base, while on the antlers themselves are only to be seen furrows more or less deep,—the vestiges of vessels formerly distributed along their surfaces when in a softer state. These hard and naked organs remain only for one year, the period of their fall varying according to the species; but, when that period approaches, there appears, on sawing them longitudinally, a reddish mark of separation between their bases and the eminence of the frontal bone, by which they are supported. This mark becomes more and more apparent till the osseous particles of that portion at last lose their cohesion. At this period a very slight shock frequently makes the antlers drop off,—two or three days commonly intervening between the fall of the one, and that of the other.

The eminence of the frontal bone, after this period, resembles a bone broken or sawed transversely, and its spongy texture is laid open. The skin of the forehead soon covers it, and, ere long, the new horns make their appearance in the form of tubercles, which continue covered by an extension of the skin, until they acquire their perfect shape and size. During the whole of this time the tubercles are soft and cartilaginous, and under the skin is a true periosteum, in which vessels, sometimes as thick as the little finger, are distributed, and penetrate the mass of cartilage in every direction. This cartilage ossifies gradually as other bones, and finishes by becoming a perfect bone. The burr at the base of the horn now penetrates the indentations through which the vessels pass, and, by its further development, first confines, and finally obstructs their flow.[1] The skin and periosteum being thus deprived of nourishment wither and fall away, and the antlers, now hard, and sharp, and bare, exist for a time in their most "palmy state," ere long, however, to shed their glory either amid the forest's gloom, or on the heathy side of sun-lit mountains. For several years successively, at each renewal, they increase in size and majesty.

It is usually in the months of March and April, when a great increase of vigour and activity is observable in these animals, that the renewal of the antlers takes place, and three weeks, or a month, are said to be sufficient for their total growth. Antlers are the characteristic marks of the male sex, the female of the rein-deer, however, forming an exception to the general rule; for, in that species, the heads of both sexes are armed.

Buffon considered the growth of antlers as a species of animal vegetation, and referred the phenomena of their production, and those attending the budding and expansion of plants, to one and the same law. This view of the matter, so much more fanciful than correct, was no doubt founded upon a limited knowledge of facts. The antlers of the stag certainly begin to shoot in the spring season, when an abundant nourishment (and, according to Buffon, so much the more reparatory in its nature, as being composed of buds containing the most active elements of vegetation!) begins to renovate the strength which the rutting season of the preceding autumn had exhausted; but, that no connection exists between the two classes of phenomena alluded to, is evident from this, that, in species of the same climate, browsing on the same kinds of herbage, the periods of the frontal accession may differ from four to five months. Besides, if the production of antlers depended on the ligneous quality of their nourishment, there would be no assignable reason for the unarmed condition of the females, none of which are provided with antlers, with the exception of that of the rein-deer,—the very species, by the bye, which is the least nourished by ligneous food. Neither can the casting of the antlers be attributed in any way, as some have imagined, to the influence of cold on the circulating system; for those of the roe are reproduced in the middle of winter, while the moulting of the stag is actually retarded by the continuance of cold. On the other hand, certain species of the South American continent lose their antlers about the period of the summer solstice. These, according to the relation of Azara, are not subject to annual loss and renewal, for he observed on the same day, three males, two of which had the antlers old and complete, while those of the other were only half grown. He adds, that not more than one-third of the males renew their antlers in each year.

---

[1] See Cuvier's *Comparative Anatomy*, Lect. ii. p. 115.

A more philosophical and better established relation has been demonstrated to exist between the growth and decay of the antlers, and the active or passive state of the generative system. The period of love in this tribe of quadrupeds so well known under the name of *rutting season*, produces a series of remarkable changes in their physical state. The reflux of the animal fluids in a direction contrary to that of the antlers, has so obvious an influence on their fall, that, in climates where the rutting season does not attain to so violent a crisis, the antlers are borne for more than a year, and castration is said to render them permanent, by extinguishing the cause of this counter flow.[1]

We shall now notice the *horns* properly so called, which are formed upon processes of bone, and which grow at their root or base, and chemically considered, bear a great resemblance to the hair, nails, and other external parts of animals. In the third month of conception, while the fœtus of the cow is still inclosed in the membrane, the cartilaginous *os frontis* presents no vestige of the horns. Towards the seventh month, however, it becomes in part ossified, and exhibits on either side a small tubercle, apparently produced by the elevation of the osseous laminæ. These bony tumours soon after appear externally. They raise the skin, which becomes callous at that part, in proportion as the tumour grows. It becomes at last horny as it elongates, and forms a kind of sheath, which covers externally the process of the frontal bone. Within this sheath there are numerous branches of blood-vessels, which serve to nourish the osseous portion. The horns, therefore, are only solid, hard, elastic, and insensible sheaths, which protect the osseous prolongation of the frontal bone. These sheaths are generally of a conical figure, and broadest at the base, the extremity from which they grow. They also present different channels or transverse furrows, which depend on the age of the animal, and denote the number of years it has lived in a very certain manner according to the species.

The texture of the horns appears to be much the same in the goat, sheep, antelope, and ox. They consist of fibres of a substance analogous to hair, which appear agglutinated in a very solid manner. In the first two genera these fibres are short, and covered by superincumbent layers like tiles. In the last two they are longer, more compact, and form elongated horns incased in each other.

The horns of the Rhinoceros already briefly alluded to, seem to differ somewhat from those of ruminating animals. They have no bony part, and are not situated on the *os frontis*, but on the lines of the nose. They are formed, however, of the same substance, and we even observe more distinctly in the horns of this animal the fibres analogous to hair. The base of the horn, indeed, presents externally an infinite number of rigid hairs, which seem to separate from the mass, and render that part rough to the touch. When sawed transversely, and examined with a glass, we perceive a multitude of pores that seem to indicate the intervals resulting from the union of the agglutinated hairs. When divided lengthways, numerous longitudinal and parallel furrows also demonstrate the same structure. This kind of horn is attached to the skin only. Those of the two-horned rhinoceros appear always in some degree movable. When fixed, as in the one-horned species, there is a thick mucus interposed between its base and the bone on which it rests.[2]

In the Giraffe or Camelopard the horns are short and cylindrical, and even in their completed state, are covered with hair, except at the points, which are more bare and callous. Their bases are dilated by very large cells, which are continuous with the frontal sinuses. These horns differ from those of the bull, antelope, &c. in this, that they are not continuations of the frontal bone, but are separated from it and the parietal, by a membranous space; at least such is the structure observable in the young giraffe which was transported to Paris by Delalande. These horns are permanent, and in relation to several of their anatomical and physiological characters, may be regarded as intermediate between the antlers of stags, and the horns properly so called, of the other tribes.

We may observe, in conclusion, that ruminating animals occur in almost all parts of Europe, Asia, Africa, and America. None are native to New Holland.

GENUS CAMELUS, Linn. Incisives $\frac{2}{6}$, canines $\frac{1-1}{1-1}$, false molars $\frac{1-1}{1-1}$, molars $\frac{5-5}{5-5}$; $= 36$. The upper lateral incisors assume the form of canine teeth, and the canines themselves are straight and strong. The head is lengthened, the upper lip cloven, the nostrils consist of two clefts capable of being opened and closed. The eyes are projecting; the ears rather small. The neck and limbs extremely long. The feet are not cloven, but are furnished beneath with a very broad horny sole, and the two toes are each terminated by a small short somewhat curved nail. There are one or more fatty humps along the dorsal region. The mammæ are four in number.

Of this remarkable genus there are two species, or at least two well marked races, usually regarded as distinct. The Bactrian species, or Camel properly so called (*C. Bactrianus*, Linn.), is distinguished by its pair of humps, one above the shoulders, and another near the rump. It is an animal of Asiatic origin, and is said still to occur in the wild state in the desert of Shamo, on the frontiers of the Celestial Empire. It is used as a beast of burden in Turkistan and Thibet, and even as far north as the shores of Lake Baikal. It is consequently capable of being acclimated without much difficulty in any temperate region, and was introduced into Tuscany by the Grand Duke Leopold, where it still breeds in the maremmas of the Pisan district.

[1] See the article *Cerf* in the *Diction. Classique d'Hist. Nat.*, t. iii. p. 371; consult also the words *Bois* and *Cornes* of the same work.

[2] *Comp. Anat.* Lect. xiv. p. 623.

Though useful as a beast of burden, it is not there employed at all extensively for the general purposes of rural labour, being chiefly occupied in carrying stores of firewood to the city. This animal is more restricted in a southern direction than the single humped species.

The other species of camel usually called the dromedary (*C. dromedarius*, Linn.), has only a single hump upon its back. (See Plate XII., figure 3.) This is now the better known and more abundant of the two, and has spread from Arabia into Syria, Persia, and all over the northern parts of Africa. The name of dromedary (from the Greek δρομεὺς), was originally applied to a swift running variety, but has in the course of time been applied to the species itself. Colonel Hamilton Smith informs us that it is the dromedary that is used in India to precede the nawabs on state occasions, and that a corps of these animals was formerly maintained by the Honourable Company, each being mounted by two men, and armed with musketoons or swivels. At particular seasons they are very savage. If we may judge from the ample covering of woolly hair by which, except towards the termination of the rutting season, both the species are clothed, we should infer that each was originally derived from a comparatively temperate clime. The southern base of the Caucasus has been by some assigned to the dromedary or Arabian species; while the arid plains beneath the northern confines of the Paropamisaden range, with the wilderness of Gasnak and Chorasmia, east of the Caspian Sea, are regarded as the native abodes of the two humped or Bactrian camel. This, it is said, may be inferred from scattered hints in the Zend, the poems of Schah Ferdusi, and from the Arabian Epic, the Romance of Antar.[1] The articles used in manufactures, and known by the names of mohair and camlets, are the produce of the fur of these animals.

Ancient authors do not seem to allude to the camel as an inhabitant of Africa. It is mentioned however in Genesis (chap. xii. v. 16) as among the gifts bestowed by Pharaoh on Abram, and it must therefore have been well known on the banks of the mysterious Nile, at a period prior to that of the most ancient of the Greek or Roman writers. It has indeed been remarked as a singular circumstance, that the Romans who waged such frequent wars in Africa, should not have thought of mentioning these animals, till Procopius noticed camel-riding Moors in arms against Solomon, the Lieutenant of Belisarius.

Genus Auchenia, Illig. Incisives $\frac{2}{6}$, canines $\frac{0-0}{1-1}$, false molars $\frac{1-1}{0-0}$, molars $\frac{5-5}{5-5}$; $=32$. Feet more cloven than in the camels, but supported behind by a small callous sole. No fatty humps upon the back. Mammæ two.

The species of this genus are peculiar to South America, where they may be said to represent the camels of the Old World. Various species have been described by Molina[2] and other writers, but naturalists seem to have failed in establishing the distinctive characters of more than two, the *lama* or *guanaco* (*Camelus llacma*, Linn.), and the *Vigogna* (*Camelus vicugna*, Linn.). Of these the former is as large as a stag. It is covered with long coarse chestnut coloured hair, of varying hue, in the domestic state. It lives in troops upon the cold and lofty ranges of the Andes, and was the only native beast of burden in Peru at the time of the discovery of that country by Europeans. The animal known as the *Alpaca* (see Plate XII., figures 4 and 5) is now regarded as a woolly-haired variety of the lama. The vigogna is of smaller size, and is characterized by a woolly fawn-coloured coat, of a texture so admirably soft and fine as to be highly prized for the fabrication of various stuffs. This species inhabits a vast extent of the Andes in the neighbourhood of the region of perpetual snow. When transported to the lower plains of Chili and Peru it becomes unhealthy, and does not long survive. It is of a more savage nature than the preceding species, and has not yet been effectively reduced to a domestic state. It is alleged never to drink. The vigogna is of a very fearful disposition, and is easily deterred from its accustomed paths of safety by a stretched cord, from which pieces of coloured rags are here and there suspended. In this state of uncertainty and terror it is not only easily shot, but will even allow itself to be approached and seized by the hind legs. Eighty thousand are said to be killed every season in the higher countries of Chili and Peru. As it is for the wool alone that they are massacred, it would probably be more politic rather to sheer than slay them.

Genus Moschus, Linn. (Male) incisives $\frac{0}{8}$, canines $\frac{1-1}{0-0}$, molars $\frac{6-6}{6-6}$; $=34$. (Female) incisives $\frac{0}{8}$, canines $\frac{0-0}{0-0}$, molars $\frac{6-6}{6-6}$; $=32$. The canine teeth in the upper jaw of the males of this genus are long, vertical, compressed, and slightly curved backwards. They protrude considerably from the mouth. (See Plate XII., figure 6.) The feet are hoofed and cloven, like those of the ordinary ruminants. The mammæ are two or four in number.

The musk deer seem confined to the temperate and southern parts of Asia, and the great eastern islands. They are remarkable for their elegant and graceful forms. Although the substance called *musk* has been known throughout Central Asia from time immemorial, it does not appear that the species which produced it was described by the ancients, or in any way identified till the days of Abuzeid Serassi, an Arabian author, who mentions it as a deer without horns. A knowledge of it seems to have been first introduced into Western Europe by Serapion, a writer of the eighth century. The musk deer, properly so called (*Moschus moschiferus*, Linn.) is nearly as large as a roebuck, and occurs over a vast extent of Central Asia, from Thibet to the vicinity of Lake Baikal. It is also frequent in many parts of India, and the mountainous provinces of the Chinese empire. The prized perfume is obtained from a small bag placed in the lower region of the abdomen of the males. There are various modes of capturing the musk deer or *che-kiang*, as it is called in the East. It is frequently shot. The sportsman, however, must climb among the mountain fastnesses like a chamois hunter, and ascend towards the most inaccessible places. It is also taken by nets and gins, or by encumbering the sides of some deep and lonesome defile by a kind of palisade of thick and prickly bushes. Several other species of this genus have been described by naturalists, such as the *napu* or Java musk (*M. javanicus*, Raffles,[3] see Plate XII., figure 7), and the beautiful Chevotrain (*M. pygmæus*), one of the smallest of the ruminating order. The body of the latter does not measure more than eight inches long. The *minima* is a Ceylonese species first described by Knox.[4]

In all the ensuing genera of the ruminating tribes, the head (at least of the males) is furnished with antlers or horns.

Genus Cervus, Linn. Teeth of the same amount as in the preceding genus; the canines of the males, however, being shorter. Branched antlers, solid and deciduous, and of greater or less extent, according to age, and the constitution of each particular kind. Mammæ four.

This genus contains those magnificent and diversified species commonly called Deer. These animals are, with few exceptions, characterized by extremely graceful forms, by light but strong proportions, and by the energy and activity of their general movements. As constituting the noblest objects of the chase, as well as affording the choicest subjects for the larder, they have long been regarded with great interest by the human race. The genus is distributed over all the greater divisions of the earth, with the exception of New Holland, and its numerous species have been formed in modern times into many minor groups, an exposition of the detailed complexities of which would be incompatible with the compendious nature of the present treatise.[1]

[4] In his *Historical Relation of Ceylon.*

Two species (the rein-deer and the elk) seem common to the northern parts of Europe and America; five or six are peculiar to North America; about an equal number occur in the New World, south of the equator; and a much greater variety inhabit India, China, and the great islands of the south-east of Asia. The generality of deer vary in colour according to age and season, and are subject to those constitutional changes which physiologists distinguish by the names of *albinism* and *melanism*,—the former applied to the white, the latter to the black varieties of colour. M. Desmoulins has remarked the singular circumstance, that the white varieties occur more frequently in equatorial regions than in the colder countries of the north; a proof, perhaps, that the intensity of light and heat are but secondary causes in the production of animal colours. We shall proceed to a brief notice of a few of the more remarkable species.

The elk (*Cervus alces*, Linn., see Plate XII., figure 9), called moose-deer in America, is the most gigantic of the genus, and is easily recognised by the great height of its limbs, the shortness of its neck, its lengthened head, projecting muzzle, and short upright mane. Its general aspect seems rather disproportioned and ungraceful. When full grown it measures about six feet in height. The fur is long, thick, extremely coarse, of a hoary brown colour, but varying considerably in hue with age and season. The antlers are of great breadth and solidity, plain along their inner or backward margins, but armed externally with numerous sharp pointed snags or shoots, which sometimes amount to nearly thirty in number.[2] A single antler has been known to weigh about sixty pounds. Although the muzzle of the elk is long and flexible, yet, owing to the shortness of its neck, it gathers its food with difficulty, or at least in a constrained and awkward posture, from the surface of the ground. Hence its propensity to browse upon the tender twigs and leaves of various shrubs and trees; a mode of feeding frequently exhibited by the individual in the gardens of the Paris Museum. In the northern parts of America elks live in small troops, and are fond of swampy places. The old ones lose their horns in January and February, the young in April and May. They were formerly found as far south as the Ohio, but at present they occur only in the more northern portions of the United States, and beyond the great lakes. Although they form small herds in Canada, they are very solitary in all the more northern districts, where two are seldom seen together except during the rutting season, or when the female is accompanied by her fawns. Sir John Franklin met with several during one of his expeditions feeding on willows at the mouth of the Mackenzie River, in lat. 69°.

This great species is one of the shyest and most wary of the deer tribe. It is an inoffensive animal, unless when irritated by a wound, or under the influence of the rutting season. When provoked, by whatever cause, its prodigious strength renders it almost irresistible, and it will kill the largest dog or the fiercest wolf in a moment by a single blow of its fore foot. It is much sought after by the American Indians on account of its flesh, which, though coarse grained, and tougher than most other kinds of venison, has a palatable flavour, somewhat resembling that of beef. The nose and tongue are particularly esteemed. The hide is of value in the making of canoes, and of several articles of dress. A fine male elk will weigh twelve hundred pounds. This animal occurs (as far as yet known, specifically the same) in several of the northern countries of Europe, especially Scandinavia, between 53° and 63°. It is also found in Asia, where it is said to advance (in Tartary) as far south as the 45°. The *ancient* history of the elk consists of but little else than a series of absurd fables. Neither the Greek nor Roman writers knew any thing of its actual existence in any of those territories which they overran, although the former received exaggerated accounts from the Scythians, the latter from the Germans, of its extraordinary aspect and character. It was said to have no joints to its legs, to have antlers growing from its eye-lids, to be incapable of browsing except when walking backwards, while its origin was traced to a productive union between the stag and camel.

Another noted species, likewise extensively distributed over the northern parts of both the Old and New World, is the rein-deer (*Cervus tarandus*, Linn., see Plate XII., figure 8). It has long been domesticated in the Scandinavian peninsula, and is an animal of indispensable importance to the forlorn families of the Lapland race. We are less acquainted with the domestic manners of the American variety, which indeed has never been rendered subservient to man. There appears to be two distinct or well marked races of the rein-deer in the fur countries of the New World. One of these is confined to the woody and more southern districts, while the other retires to the woods only during the winter season, and passes the bright but fleeting summer either in what is called the barren grounds, or along the shores of the Arctic Ocean. Those of the barren grounds are small of stature, and so light that a hunter can carry a full grown doe across his shoulders. Sir J. Richardson is of opinion that when in prime condition the flavour of its flesh is superior to that of the finest English mutton. He was probably hungrier in America than he has ever been at home. The other variety is much larger, and is usually called the woodland caribou. It is, however, much inferior as an article of diet. One of the most remarkable peculiarities of this animal is that it travels *southwards* in the *spring*, crossing the Nelson and the Severn Rivers in vast herds during the month of May, with a view to spend the summer on the low marshy shores of James's Bay, and returning inland, in a *northerly* direction, in September. The provision called *pemmican*, so essential to the subsistence of our Arctic travellers, is formed by pouring one-third part of melted fat over the flesh of the rein-deer, after it is dried and pounded. We may add, that of all the cervine animals of America, this species is the most easily approached, and immense numbers are annually slain by the Indian hunters. Indeed, the very existence of several of the native northern tribes may be said to be linked to that of the animal in question.

The European rein-deer, in its domestic state, is of infinite advantage to the Laplanders, serving at once as a substitute for the horse, the cow, the sheep, and the goat. Several attempts have been made to introduce it into Britain, but without any permanent success. It would probably succeed better among the rocky hills of the Hebrides than in the more luxuriant pastures of the south. Those introduced by Sir H. G. Liddell, in 1786, although some of them produced young, and gave promise of a healthy life, died of a complaint similar to the *rot* in sheep. This was attributed to the richness of the grass on which they fed. A buck rein-deer lived nearly three years not far from Hackney. He was kept in a close of about an acre, the grass of which was rich, and he fed constantly on it throughout the year, though much fonder of a small supply of *lichen* which was sent over from Norway, and which, extremely abundant on almost all the rocky grounds of Scandinavia, constitutes his natural food. He would fondly follow any one who held even a shred of it in his hand. When put into a garden where there existed a considerable variety both of flowering shrubs and forest-trees, the individual in question was observed to browse upon them all except the elder. He drank a great quantity of water. This animal cast his antlers in winter for two successive seasons, and renewed them in the spring. During one of these years they continued in the state of stumps till the 30th of January, when they began to shoot; on the 24th of February they were five or six inches high, and covered by a deep pile of velvet hair. It may possibly be unsafe to reason generally from one individual in a state of confinement; but this account does certainly not agree with that of Leems, who, in his ninth chapter, states that the rein-deer loses his horns in spring. Both Hoffberg and Buffon indeed assert the contrary, yet, as Leems lived ten years in Lapland, his opportunities of personal observation must have exceeded those of all other naturalists; and we may add, that his account is more consistent with the fact mentioned by so many travellers, that the rein-deer makes use of its brow antlers to remove the snow from the ground in winter; a circumstance also recorded by several of those very compilers who at the same time, with characteristic inconsistency, deny the animal its antlers during that inclement season. Leems, however, expressly says that the rein-deer procures the lichen by means of its feet. He adds, that it also kills a great quantity of mice, of which it devours the heads with great avidity,—a most singular propensity in a ruminating animal.[1]

---

[1] For an ample account and classification of the antlered ruminants, see Griffith's *Animal Kingdom*, vols. iv. and v.

[2] The antlers as represented by the figure last referred to are immature.

Contrary to the usual rule, the female rein-deer is provided with horns, as well as the male,—a fact mentioned by Julius Cæsar, who records the species as an inhabitant of the Hercynian forest, that "boundless contiguity of shade" which is supposed to have extended as far as the Uralian Mountains. In truth, a vast quantity of rein-deer horns are still found in the sandy banks of the Olenia, a stream which flows into the Wolga, about forty wersts below Sarepta. Pallas observes that the steppes to the east of the Wolga were of old clothed with forests; and herds of wild rein-deer are still found among the pine woods which stretch from the banks of the Oufa, under the fifty-fifth degree, to those of the Kama. They proceed even farther south, along the woody summits of that prolongation of the Uralian Mountains which stretches between the Don and the Wolga, as far as the forty-sixth degree. The species thus advances almost to the base of the Caucasian Mountains, along the banks of the Kouma, where scarcely a winter passes without a few being shot by the Kalmucks, under a latitude two degrees to the south of Astracan. This remarkable inequality of the polar distances in the geographical positions of this species, according to the difference of meridian, is of course dependent on the laws which regulate the distribution of heat over the earth's surface, as explained by Humboldt.[2] It is well known that physical climates do not lie, as it were, in bands parallel to the equator, but that the isothermal lines recede from the pole in the interior of continents, and advance towards it as we approach the shores. It follows that the farther any northern animal is naturally removed from the ameliorating climatic influence of the ocean, the more extended may be its range in a southerly direction.[3]

We can here scarcely do more than name the wapiti or Canadian stag (*Cervus canadensis*, Gmelin, *C. strongyloceros*, Schreber), described under the name of red-deer by Mr Warden. It is not, however, specifically the same as the animal so called in Britain, being about a fourth larger, and farther distinguished by the extreme shortness of its tail. According to Hearne, it is the most stupid of all the deer tribe.

The fallow-deer (*Cervus dama*, Linn.) of our inclosed parks, is now scarcely known except in the domestic state. Some incline to regard it as originally an African species, in consequence of an individual having been shot some years ago, apparently wild, in a wood to the south of Tunis. It is easily distinguished from our native red-deer, by its smaller size, its longer tail, and the palmation or breadth of its antlers, a character which induced its ancient name of *platyceros*. It is very common in the southern countries of Europe, but rare in Sweden and other northern regions. According to Linnæus it does not occur in the latter country except in the parks of the king and the nobility, although it sometimes escapes by chance into the forests. It is said to be now frequent in the forests of Lithuania, from whence, according to Raczinsky, the parks of the Polish nobles were in use to be supplied. But it is not included by Pallas in his Catalogue of Russian Animals.[1] In Livonia it requires to be sheltered during the winter season. It abounds in Sardinia, and in several of the Greek and other islands of the Mediterranean. The evidence of its existence in the higher countries of Asia, and onwards through the Chinese dominions, is too obscure to be depended on as truly applicable to this particular species. If not indigenous to France and Spain, the period of its introduction to these countries must have been remote. Two permanent varieties seem to exist in Britain, viz. a spotted kind supposed by Pennant to have been transmitted from Bengal, and a kind of a dark brown colour alleged to have been introduced by James I. from Norway into Scotland, and thence transported to the chaces of Enfield and Epping. It is possible that the existence of the spotted species called Axis in India, may have led to the first idea,—presumed to be erroneous from the fact of the *spotted buck* being noticed in Gwillims' *Heraldry* (4th edition, 1660), where it is quoted as being borne on ancient coats of arms, at least anterior to British intercourse with the east; and it may perhaps militate against the introduction from Norway of our darker brown variety, that Pontoppidan, in his natural history of that country, makes no mention of fallow-deer of any hue whatever.

[2] In the *Memoires d'Arcueil*, t. iii.

[3] Although we have already assigned a greater space to our notice of the rein-deer than our limits can well afford, we yet cannot refrain from here alluding to a curious point in what may be called the literary history of the species, which, till it was cleared up by the sagacity of Baron Cuvier, had greatly perplexed the naturalist. It was an opinion very generally received, that the reindeer had existed in France, at least in the Pyrenees, as late as the fourteenth century; which opinion brought along with it several others regarding the changes of temperature which bad taken place in Europe, and the origin of many fossil bones. It was first broached by Buffon, however contrary it may seem to his own system, which maintains the gradually increasing coldness of our globe. "Quinze siecle," says Buffon (xii. 83), "après Jules-Cesar, *Gaston Phœbus* semble parler du renne sous le nom de rangier, comme d'un animal qui auroit existé de son temps dans nos forets de France," &c. This Gaston Phæbus was Gaston III. Count of Foix and Lord of Bearn, born in the year 1331, and author of a book entitled, *Le Miroir de Phebus des deduits de la Chasse*, in which the rein-deer is described with tolerable accuracy. As Gaston de Foix's territories lay at the foot of the Pyrenees, it was hence inferred that he had there seen the animal in question; and on this erroneous supposition the Count de Mellin, Schreber, and others, have proceeded in their history of the species. It first occurred to Cuvier to compare the different early editions of the work, to see if any thing could be thereby elicited; but the most beautiful, that of Antoine Verard, led him farther from the truth than ever. He there found the following passage: *J'en ai veu en Morienne et Pueudeve oultre mer, mais en Romain pays en ay je plus veu.* Of course, the existence of the rein-deer in Mauritania would have been still more extraordinary than at Béarn. He next had recourse to a search among the manuscripts of the royal library, where he fortunately found the original of the work in question, as presented by Gaston himself to Philip the Bold, Duke of Burgundy; and on referring to the particular passage, he found all obscurity at once removed. It is there clearly written: "J'en ai veu en *Nourvegue* et *Xuedene* et en ha oultre mer, mes en Romain pays en ay je peu vus." Now, Norway and Sweden were the very countries of which the rein-deer had been described as an inhabitant by Albertus Magnus, about a century before the time of Gaston, and where, we need scarcely say, they still exist in great abundance. The interest which this inquiry excited induced an examination of Froissart and other ancient chroniclers, from whom it appeared that Gaston de Foix, as was usual for the cavaliers of the fourteenth century, had at an early age joined a crusade in favour of the distressed Teutonic knights against the Paynims of Lithuania; that he was passionately fond of hunting, usually entertained 1600 dogs, and at last died of fatigue in consequence of his exertions in pursuing a bear. Hence Cuvier naturally inferred, that after his journey into Prussia, he had been induced, by curiosity or the love of sport, to cross the Baltic Sea and traverse Scandinavia, where the numerous troops of reindeer could not have failed to attract the notice of "a mighty hunter." There is therefore no reason whatever for supposing that this species ever inhabited the mountains of the Pyrenees, or any of the southern countries of Europe. See Cuvier's *Note sur la pretendue existence du Renne en France dans le moyen age*, read to the Institute, and published in the *Ossemens Fossiles*, t. vi. p. 119 (of the 4th edition, 1835).

The stag or red-deer (*Cervus elephas*, Linn.) is the most stately and magnificent of all the wild animals still indigenous to Britain. Vast herds continue to range the mountains in various parts of Scotland, and the species is not unfrequent in the larger of our western islands, such as Mull and Jura. In the southern quarters of the island, the breed is almost extinct in the wild state. It is a shy and wary creature, finely endowed with the sense of smell, not easily approached by the hunter, even from the leeward, and extremely dangerous to encounter closely, from its great strength and occasional courage. Many instances are recorded of its having killed both men and dogs, and one is known of its having beat off a tiger which was let loose upon it in an inclosed area, at the instance of William duke of Cumberland. Its flesh, though lauded by Dr Johnston, and by no means to be despised by a hungry sportsman in the wilds of Scotland, is in our opinion poorer and less highly flavoured than that of the fallow-deer. Of course it is not so easily *selected*, or in any other way obtained in prime condition, and the necessity of eating it occasionally when lean and tough may possibly have proved injurious to its culinary character. Both sexes of the red-deer have obtuse canine teeth in the upper jaw. The age of a stag may be pretty easily determined by the branches of the antlers till its seventh or eighth year; but after that period the increase of those parts is not subjected to any fixed rule. The oldest have seldom more than ten or twelve branches, though an instance has occurred of there being thirty-three on each antler.[2] According to Cuvier, the older the individual, the deeper are the furrows of the antlers.

The only other British species of the deer tribe is the roe (*Cervus capreolus*, Linn.). This beautiful animal, so well known to the Scottish sportsmen, is believed to be now extinct in the southern portions of the kingdom.[3] It differs from the generality of the deer kind in not being gregarious, seldom more than a single family being found together. The roe rarely measures above two feet in height, with a length of about three feet four inches. The antlers are about eight inches long, and are usually divided at the top into three branches. The colours of the fur vary with the season, being bright tawny-brown in summer, in winter more grizzled and obscure. The hair is long, and when inspected minutely, is found to be generally ash-colour at the base, black towards the point, with the point itself yellow. The rump and lower parts are white. This species is certainly confined to the Ancient World, although by a misapplication of the name, it has been believed by many to occur in America. It is common in Scotland, and is found pretty generally, though not in great abundance, in what may be called the Central Zone of Europe. It is rare in France, and is known to have been almost entirely extirpated from Burgundy during the cold winter of 1709. The places where it loves to dwell are woody districts, varied by open glades, and broken in upon by land capable of cultivation. It does not ascend those sterile mountain tracts where the red-deer is so often found. According to Captain Williamson, the roe occurs on the borders of Bengal, particularly among the crags and ravines of the western frontier.

We shall now notice a very few of the more southern foreign species. It has been observed in general, that few of these change their colours with the season. Several magnificent examples of this tribe of animals are to be found on the southern sides of the Nepaul Mountains. Of these we have here exhibited the Nepaul stag (*Cervus Wallichii*, Plate XIII., figure 1), a species which in many respects exhibits a resemblance to the red-deer of our native heath-clad mountains. We scarcely know, as yet, of any other individual than that brought down by Dr Wallich to Calcutta. A drawing was made of it in the living state, by a native artist, and transmitted by M. Duvaucel to Paris, where it was published by M. F. Cuvier. The horns are shorter and less magnificently branched than in the Scottish species, but they have been supposed to have been dwarfed, in the individual in question, by the decrepitude of age. Each has a pair of small brow antlers at the base, and somewhat more than half way up the beam, a small snag turns forwards.

The *Rusa* group of stags is entirely Asiatic, and is distinguished by rounded horns, with a brow antler, but without any median or besantler, and the beam terminates in a single perch, with a snag more or less elongated, placed midway or higher on its anterior or posterior edge. The great Rusa (*Cervus hippelaphus*, Cuv.) almost equals the height of a horse. It has trifurcated horns, and very coarse fulvous brown hair, which changes to a greyer hue in winter. The tail is rather long, and there is no disk on the buttock. This species seems to correspond to the great axis of Pennant. It occurs in several of the Asiatic islands, and in Continental India is found chiefly in the Jungleterry district of Bengal. The exact nature of the animal described by Aristotle under the name of ἵππελαφος, has been a subject of some controversy. The term was formerly applied to a species which occurs in the forests of Germany; but, according to the researches of M. Duvaucel, it is undoubtedly the black deer or black rusa of Bengal (*Cervus Aristotelis*, Cuv.). Its horns are forked at the extremity, and bear only a single branch at the base, similar, as Aristotle expressed it, to those of a roe. It inhabits the Prauss jungles, and is known by the name of *Saumer*.

---

[1] See the *Ossemens Fossiles*, t. iv. p. 29.

[2] We allude to the animal killed by the king of Prussia in 1669, and presented to Augustus I. Elector of Saxony and King of Poland. According to Bechstein, the head is still preserved at Moritzburg.

[3] "The particular periods, therefore, when the wolf and wild boar became extinct in this country cannot with precision be accurately ascertained; but the history and fall of the roebuck are better known. It continued to be an inhabitant of England till within the last century, and was not unfrequently met with on the wastes, a small distance from Hexham, in Northumberland. As the breed, however, became gradually more scarce, it was sought for with greater eagerness; so that after enduring the united attacks of the dog and gun for a few seasons, it at length dwindled away into one solitary animal, which about forty years since is said to have been destroyed by —— Whitfield, Esq. of Whitfield, in Northumberland."—*The Sportsman's Cabinet*, vol. ii. p. 172.

The male is nearly as large as an elk (which name, indeed, is erroneously applied to it by many Anglo-Indians), and is represented by British sportsmen in the east as extremely vicious as well as strong. Its prevailing colour in summer is dark brown, in winter nearly black. The abdomen, and a ring around the mouth and nostrils, are whitish, the insides of the legs fawn colour. Captain Williamson describes it as attaining to the dimensions of a Lincolnshire cart-horse (fifteen or sixteen hands high), of a shining black colour, with tan points; the female mouse-coloured.

The spotted axis of India (*Cervus axis*) resembles the fallow-deer, but is easily distinguished by the roundness of its horns, and the want of a terminal palm. The female, however, greatly resembles the doe of our domesticated species. This kind is most frequent in Bengal, and on the banks of the Ganges, although it occurs throughout India, as well in the Eastern Archipelago. It has been frequently imported into Europe, and breeds freely both in France and England. The sense of smell is extremely refined in the spotted axis,—so much so, that although extremely fond of bread, it refuses to eat a piece that has been previously blown upon,—so at least states M. F. Cuvier, regarding the individual observed in the Paris garden. Its disposition in the captive state is otherwise remarkably mild and accommodating.

Passing over the *Muntjaks*, which are numerous in India and the Eastern Islands, we come to a very peculiar animal, the Giraffe, constituting the

GENUS CAMELOPARDALIS, Linn. Incisives $\frac{0}{8}$, canines wanting molars $\frac{6-6}{6-6}$; $= 32$. Head lengthened, with a bony tubercle on the middle of the face, and two bony projections on the forehead, covered by the fur, and terminated by a tuft of longer hairs. The fore-quarters are very high in comparison with the hinder, and the dorsal line is consequently oblique. The neck is of extraordinary length, and the limbs are slender, and terminated by cloven hoofs, resembling those of the ordinary ruminants. There is a callosity on the sternum. The mammæ are four in number.

The giraffe or camelopard, the tallest, and in many other respects one of the most remarkable of quadrupeds, is entirely peculiar to the African continent. Its appearance is too familiar in books of natural history to require a detailed description. (See Plate XIII., figure 4.) We shall merely mention that it measures from fifteen to twenty feet in height, including the lengthened neck. It is a timid and gentle animal, browsing habitually on the foliage of trees, especially those of the Acacia and Mimosa tribes. Its gait or mode of progression is thus described by Mr Lichtenstein: "We had hardly travelled an hour when the Hottentots called our attention to some object on a hill not far off on the left hand, which seemed to move. The head of something appeared almost immediately after, feeding on the other side of the hill, and it was concluded that it must be that of a very large animal. This was confirmed, when, after going scarcely a hundred steps further, two tall swan-necked giraffes stood almost directly before us. Our transports were indescribable, particularly as the creatures themselves did not perceive us, and therefore gave us full time to examine them, and to prepare for an earnest and serious chase. The one was smaller, and of a paler colour than the other, which Vischer immediately pronounced to be a colt, the child of the larger. Our horses were saddled, and our guns loaded in an instant, when the chace commenced. Since all the wild animals of Africa run against the wind, so that we were pretty well assured which way the course of these objects of our ardent wishes would be directed, Vischer, as the most experienced hunter, separated himself from us, and by a circuit took the animals in front, that he might stop their way, while I was to attack them in the rear. I had almost got within shot of them when they perceived me, and began to fly in the direction we expected. But their flight was beyond all idea so extraordinary, that between laughter, astonishment, and delight, I almost forgot my designs upon the harmless creatures' lives. From the extravagant disproportion between the height of the fore to that of the hinder parts, and of the height to the length of the animal, great obstacles are presented to its moving with any degree of swiftness. When Le Vaillant asserts that he has seen the giraffe trot, he spares me any farther trouble in proving that this animal never presented itself alive before him.[1] How in the world should an animal so disproportioned in height before and behind trot? The giraffe can only gallop, as I can affirm from my own experience, having seen between forty and fifty at different times, both in their slow and hasty movements, for they only stop when they are feeding quietly. But this gallop is so heavy and unwieldy, and seems performed with so much labour, that in a distance of more than a hundred paces, comparing the ground cleared with the size of the animal and of the surrounding objects, it might almost be said that a man goes faster on foot. The heaviness of the movement is only compensated by the length of the steps, each one of which clears, on a moderate computation, from twelve to sixteen feet."[2] A tolerably good horse overtakes the giraffe without difficulty, especially over rising ground.

That there is more than a single species of camelopard, is a point rather surmised than demonstrated by our modern naturalists. Some are inclined to infer, chiefly we presume from the difference in their geographical position, that the southern kind, so frequently alluded to in the travels of Le Vaillant, Burchell, and others, are probably distinct from those seen during the expedition of Denham and Clapperton, and more recently described by Ruppel. Camelopards were well known to the ancients, and were shewn in the Circæan Games by Cæsar the Dictator. The Emperor Gordian afterwards exhibited ten at a single shew; and tolerably accurate figures of these extraordinary creatures, both in a browzing and grazing position, have been handed down by the Prænestine pavement. During the darker ages, and indeed for some centuries after the revival of learning, they seem to have been unknown to Europeans; but about the middle of the sixteenth century, the Emperor of Germany, Fredericus Ænobarbus, received one from the Sultan of Babylon. Lorenzo de Medicis was also presented with a live specimen by the Bey of Tunis. Nearer our own times, the camelopard is described in a letter from Captain Carteret to Dr Maty, as having been killed in a journey from the Cape, in 1761;[3] yet the first statements of the unfortunate but accurate Vaillant were almost discredited till he transmitted the giant spoils to Europe. Very recently several live specimens have been transmitted from Kordofan to the gardens of the Zoological Society of London, and they have since bred in England.

GENUS ANTILOPE, Cuv. Incisives $\frac{0}{8}$, canines wanting, molars $\frac{6-6}{6-6}$; $= 32$. Bony nucleus of the horns solid like those of deer. Form light, and well adapted for great swiftness.

This numerous and varied genus has been recently divided into many minor groups, chiefly in accordance with the form of the horns. Of the far greater number Africa is the native country. These creatures are by many regarded as the most lively, graceful, and beautifully proportioned of the brute creation. They have indeed attracted the admiration of mankind from the earliest ages, and the beauty of their dark lustrous liquid eyes has afforded a constant theme for the imagination of the eastern poets. Their names are of frequent occurrence in the most ancient mythologies, and their figures are represented among the oldest of the astronomical symbols. Naturalists are more or less acquainted with about sixty species,—a few of which we shall here briefly notice.[1]

---

[1] We have elsewhere observed, that it would have been more becoming and equally logical in Mr Lichtenstein to have inferred rather that Le Vaillant misapplied the term which he made use of to designate the movements of the camelopard, than that he imagined himself to have seen an animal alive which had never presented itself to him in that condition.

[2] *Voyage au Cap de Bonne Espérance.*

[3] See *Phil. Trans.* 1770.

The antelope, commonly so called (*Antilope cervicapra*, Pallas, Plate XIII., figure 5), is an eastern species, distinguished by the triple curve of its annulated horns. These parts are extremely sharp pointed, and in India offensive weapons of great power are made, by joining two pair together at their bases. " Thus are they doubly armed." The female is hornless.

The gazelle, or Barbary antelope (*A. dorcas*, Linn.), is somewhat less than our own roebuck. The horns are black, round, lyrate, with numerous rings, and measure about a foot in length. It is widely spread over northern Africa, and occurs in Persia and the southern parts of Syria. It is a gregarious species of great beauty, much esteemed by lions and other beasts of prey, and although in many respects well known to naturalists, it is yet difficult to draw a precise distinctive line between it and several other closely allied kinds, such as the *kevel*, the *korin*, and the *tzeiran* of the Persians. The gazelle is accurately described by Ælian under the title of *dorcas*, a name bestowed by other ancient writers on the roe. This is the species which, by reason of its exquisite grace and beauty, affords so continued a subject of comparison, and is so often used as a poetical image by eastern writers.

> " Her eyes dark charms 'twere vain to tell,
> But look on those of the gazelle,
> They will assist thy fancy well."

We have figured the head (Plate XIII., figure 3), of a closely allied species called the corinne (*Ant. corinna*, Gmelin). It differs from the gazelle chiefly in having more slender horns. " Ce n'est peut être," says Cuvier, " qu'une variété de sexe."

The Chinese antelope, or Dzerin, of the Mongolian Tartars (*A. gutturosa*, Pallas), is of a heavier form than the preceding, with short thick horns, reclining backwards, divergent, wavy, and the points turned inwards. One of its chief characteristics is a large moveable protuberance on the throat, occasioned by a dilatation of the larynx,—particularly observable in the old males. This is the species known in China by the name of Hoang-yang, or the yellow goat. It occurs also in the deserts between the celestial empire and Thibet, and extends eastward into Siberia, and over that vast expansion so vaguely known under the name of the Desert of Cobi. It is said to avoid woody places, and to prefer open plains and barren mountains. It is an animal of great swiftness, and long endurance of fatigue.

The oryx or algazel (*A. leucoryx*, Lich.? *A. gazella*, Linn. Plate XIII., figure 2) measures above three feet and a half in height at the shoulder. The body is rather bulky, the limbs slender, the horns of the male horizontal, bent backwards, obliquely annulated, with smooth tips, and nearly three feet long. It inhabits sandy districts in Persia and Arabia, and has been shot on the western side of the Indus, in the deserts of the Mekran. We may here notice a remarkable species called the *chiru* (*A. kemas*? Smith), an inhabitant of those inaccessible and piny regions of Chandang which verge on the eternal snows of the Himmaleh Mountains. It sometimes occurs with only a single horn, and in that accidental or imperfect condition is supposed to have given rise to the belief in *monocerotes* or unicorns,—animals which all who are conversant with the structure of skulls, and the position of the frontal sutures, are well aware cannot exist in any accordance with the general laws of organic form. This species is remarkable also for an abundant coating of wool,—a provision bountifully connected with its position as a mountain dweller in a cold and icy clime. The Caffrarian oryx (*A. oryx*) is not more remarkable for beauty of form than for its great strength and vigour. It dwells in elevated forests, and among rocky regions in Southern Africa, and is exceedingly fierce during the rutting season, especially when wounded. A friend of Colonel Smith's having fired at an individual of this species, it immediately turned upon his dogs, and transfixed one of them upon the spot. They are said to afford the best venison of any of the antelopes of Southern Africa.

The blue antelope (*A. leucophæa*) though formerly an inhabitant of the Cape colony, is now so rare in Southern Africa, that it is said no specimen has been killed there for more than thirty years. A very large species called the roan antelope *(A. equina)* was found by Mr Burchell among the mountainous plains in the vicinity of Lattakoo. The springer antelope *(A. euchore)* is called spring-bock by the Dutch. It inhabits the plains of Southern and Central Africa, and, during its migratory movements, congregates in such vast flocks as for a time utterly to destroy vegetation. The lion has been observed to accompany their onward journey, walking like a grizzly tyrant in the midst of a dense phalanx of these beautiful but fearful creatures, and with only as much space between him and his victims as the irrepressible terror of those immediately around him could obtain by pressing outwards. Mr Pringle calculated that he had sometimes within view not less than 20,000 at a time.

Among the more remarkable of the African antelopes are those called *guevei (A. pygmæa,)* which seem to consist of two well-marked varieties, if two distinct species have not been confounded under a single name. Of the smaller variety we remember a female in Mr Bullock's museum which scarcely exceeded the dimensions of a large rat, and its legs were no thicker than a goose's quill. The gueveis are generally brought from the coast of Guinea, although they have sometimes been observed to occur in the vicinity of the Cape of Good Hope. In illustration of another beautiful form of this varied genus, we have represented the species commonly called, from its peculiar markings, the harnessed antelope (*A. scripta*, Pallas, see Plate XIV., figure 1). It was seen by M. Adanson in the interior of Senegal, and few additions have been made to its subsequent history.

In the forests of Hindustan we find the *chickara* or four-horned antelope (*A. chickara*, see Plate XIV., figure 4). General Hardwicke informs us that this species inhabits woody and hilly tracts along the western provinces of Bengal, Bahar, and Orissa. It is described as a wild and agile creature, incapable of being tamed unless when taken young. It is about twenty inches in height, and two feet nine inches in length. The larger pair of horns are smooth, erect, slightly inclined forwards, somewhat divergent, and about three inches long. About an inch and a half in front of these arise a short stumpy pair, about an inch and a half in circumference, and scarcely an inch high.[2] A nearly allied, if not identical species, has been described by M. de Blainville under the title of *A. quadricornis*.[3]

The *nyl-ghau* (*Ant. picta* and *tragocamelus*, Gmel., Plate XIV., figure 3) departs greatly from the form of the true antelopes, and merges on that of the bovine tribes. Its eastern name signifies *blue ox*, and it is in fact never considered as an antelope by native observers, though so classed by European naturalists. This species was unknown to the ancients, and one of the first authentic notices of it is that by Dr Parsons.[1] Lord Clive transmitted a pair to England from Bombay in 1767, and these bred regularly for several years. The nylghau is not generally distributed over the Peninsula of Hindostan, but it occurs in the districts of Kamaghur in Central India, and is known to spread from thence to the foot of the Himmaleh Mountains. Bernier describes it as one of the objects of the chace which delighted the Mogul Emperor Aurengzebe, during his progress from Delhi to Cashmere. It is a treacherous animal, vicious, and full of vigour, and apt to prove a dangerous neighbour even in the domestic state. It may, however, be completely tamed.

---

[1] For a summary of the species, with indications of the various sub-generic groups, by Colonel Hamilton Smith, see the *Synopsis of Mammalia*, forming the fifth volume of Griffith's *Animal Kingdom*, so frequently before referred to. For numerous important observations, and a great deal of general information regarding the antelopes, consult also the fifth volume of the same work.

[2] *Linn. Trans.* vol. xiv.

[3] *Journal de Phys.* Aout, 1818.

An antelope of a still more anomalous form is the *gnu* (*Ant. gnu*, Gmel., Plate XIV., figure 5). It appears as if it were compounded of various other species, being maned like a horse, with the limbs of a stag, and the horns of a buffalo. It forms, with the brindled gnu and another nearly related species, the genus *Catobeplas* of Colonel Smith, by whom it is arranged among the bovine tribes. It assembles in large herds in the southern deserts of Africa, but is not now found nearer the Cape than the Great Karoo district. The other species spread into the country of the Caffres, and the interior deserts.

We shall conclude our meagre notice of this great genus with the only species indigenous to the central countries of the European continent, the celebrated chamois, *Ant. rupicapra*, Linn. (See Plate XIV., figure 2.) This animal measures rather more than three feet in length, with a height of about two feet and a few inches. It is distinguishable from all the other species by its short smooth black horns, rising perpendicularly from the forehead, and suddenly hooked backwards at their extremities. It inhabits the lofty mountains of Switzerland, Piedmont, and Savoy, the Pyrenees, various parts of Germany, Greece, and some of the Mediterranean islands. The sterile valleys and broken rocky grounds in the vicinity of regions of perpetual snow, form the chamois' favourite places of abode. It is much sought after for the sake of its excellent flesh, and occasionally by amateur sportsmen on account of the exciting nature of its pursuit, carried on amid scenes of great wildness and sublimity, and not unattended by danger, from the rugged or precipitous character of the ground, the deceptive ravines of ice, and the falling masses of mountain snow.

As intermediate between the antelopes and the ensuing genus, we shall here place a species which has been dignified by a great variety of names, we mean the Rocky Mountain goat (*Aplocerus lanigera*, Smith, *Capra Americana*, Richardson), by some called the wool-bearing antelope. It inhabits the highest and least accessible summits of that great range of North American mountains from which it has derived its best known name. It is equal in size to a large sheep, its colour white, and its whole body, particularly the back and hinder quarters, covered by an ample coating of long fine wool, but greatly intermixed with coarser hair. The importation of this species into the alpine or insular districts of Scotland has been recommended as an interesting experiment, not likely to be attended by much difficulty, and which might probably lead to valuable results.[2] The precise extent of its territorial range has not yet been ascertained, but it is known to occur from the 40° to the 64° or 65° of north latitude. It is scarcely ever seen at any distance from the mountains, and is said to be less numerous on the eastern than the western slopes of its native range. Its flesh is rather hard and dry, and somewhat unsavoury from its musky odour.

GENUS CAPRA, Linn. Incisives $\frac{0}{8}$, canines wanting, molars $\frac{6-6}{6-6}$; $= 32$. Horns directed upwards and backwards, compressed, transversely furrowed, their nucleus communicating by means of cells with the frontal sinus. No lachrymal sinus, nor inguinal pores. Chin generally bearded. Outline of the face straight, or rarely convex. Two inguinal mammæ.

The species which constitute the goat genus, although of less elegant form than many of the antelope tribe, are yet not undistinguished by considerable ease and gracefulness of movement; and the rocky heights on which they are so often seen no doubt add to their picturesque and imposing aspect. Although extremely docile, and fond of being caressed by human associates, they yet cease not to retain a certain degree of independence not observable in other cattle. Considered intellectually, they hold a high station in the animal kingdom. Buffon has greatly embroiled the history of these and the allied genera, by supposing that the species called the boquetin (*Capra ibex*) was the origin not only of all our domesticated sheep and goats, but of the chamois and several other antelopes. His paradoxes were first exposed by Pallas,[3] who traced the separation of the goats from the antelopes on the one hand, and from the sheep on the other, and pointing out the various species of the first named genus, shewed that our domesticated kind was derived not from the ibex, but from another wild species called *ægagrus*, an inhabitant of the Caucasian Mountains. He admits, however, in relation to certain varieties, the probability of a cross with the ibex.

The wild goat (*Capra ægagrus*, Gmelin, see Plate XV., fig. 2), the admitted source of our domestic kinds, although believed by some to inhabit the Alps of Europe, is more distinctly known as a native of the mountains of Persia and the Caucasus, where it is known by the name of *paseng*, and from whence it spreads through a great extent of northern Asia to the frontiers of the celestial empire. It is also the *bezoar* goat of the oriental nations, so called from a peculiar concretion sometimes found in the intestines. The male is larger than the usual size of our domestic species, and his horns, which form an acute angle in front, with a rounded back, and transverse ribs, are nearly three feet long. The head is black in front, the beard brown, and the general colour of the body brown and grey, but varying with the season.

The semi-domesticated varieties are too numerous to be here described. Of these the most famous is the Cashmere breed, from the coat of which the celebrated shawls and other articles are manufactured. The fleece is long and of a silky texture, straight and white. The most esteemed is the produce of Thibet, from which country it is exported to Cashmere, where 16,000 looms are constantly employed, each affording occupation to three men, and yielding together about 30,000 shawls per annum. A single fine shawl, of a rich pattern, requires for itself about a year in making.[4] The Thibet variety is chiefly remarkable for the excessive length of its silky covering, which falls in ample clusters from each side of the back, with a dorsal line of separation, and measures above a foot and a half. Its general colour is brown, with the points of a golden fulvous hue. The males of both these eastern breeds have very large flattened wavy horns. They have been introduced alive to France and England.

A beautiful dwarf variety, originally from western Africa, and commonly called the Guinea goat, is also well known in this country. The goat of Angora resembles the Cashmere kind in its flowing fleece, the locks of which, however, instead of being straight, assume the form of beautiful spiral ringlets The *Jemlah goat*, an inhabitant of the highest

Pecora.

Pecora.

range of central Asia, and that called *Jahral* in the Nepaul country, seem to present the characters of distinct species. The latter is bold, capricious, and irascible, but it is easily tamed, and thrives well when transported to other countries.[1]

The bouquetin of the European Alps (the stein-bock of the Germans, *Capra ibex*, Linn.) is a large, powerful, and extremely active animal, almost five feet in length, and nearly three feet high. The colour is greyish fawn-colour above, whitish below, with a deep brown line along the dorsal region. The female resembles the male, except in the diminished size of her horns. This species dwells among the highest and most precipitous peaks of the Alps of Switzerland, Spain, and other lofty ranges, far surpassing the chamois in the boldness with which it bounds from crag to crag, and ascending to perilous heights where even that alpine species is never seen. It is said, when springing from a great height, to bend its head between its fore-legs, in such a manner as to break its fall by alighting on its horns as well as hoofs. It is easily tamed when taken young, and breeds freely with the domesticated goats. It is alleged to do so, indeed, even in a state of nature,—for it is the general opinion of the shepherds of the Alps and the Pyrenees, that all the great he-goats which act as leaders to the flocks are either genuine bouquetins, or immediately descended from that powerful species. We believe that all that has been stated as to the occurrence of the paseng or *œgagrus* (we mean the true wild-goat) in Europe, owes its origin to the existence of a cross breed between the goat and bouquetin. The latter is likewise an Asiatic animal, and was seen by Pallas in the mountains of Siberia,[2] but the Caucasian ibex, described by Guldenstaedt is a distinct species.[3] The maned bouquetin of Africa, erroneously so called, is undoubtedly an antelope, figured by Mr Daniel under the title of *Takhaitze*.[4]

GENUS OVIS, Linn. Teeth as in the preceding genus. Horns thick, angular, transversely furrowed, spirally twisted in a lateral direction, the points more or less recurving forwards. Chin seldom bearded. Outline of the face arched or convex.

The leading fact in the geographical history of this genus is, that it occurs both in the New and the Old World, whereas the goat tribe are naturally unknown in America.

We cannot here enter into any detailed history of the numerous varieties of the domestic sheep which have resulted from the almost immemorial subservience of this animal to the human race, but must confine ourselves to a slight sketch of the features and characteristic habits of the several wild races which inhabit the different regions of the earth. Although this invaluable species is usually regarded by naturalists as being not only specifically but generically distinguished from the goat, we incline to think that the latter, or generic separation, is founded chiefly upon characters which have arisen from the influential power of man. In a state of nature, the sheep is scarcely less active or energetic than the goat,—its dimensions are fully greater,—its muscular strength at least equal, both in force and duration. It is also an alpine animal, fearless of crag and cliff, and dwells indeed by preference among the steepest and most inaccessible summits of lofty mountains. Among its native fastnesses it is seen to bound from rock to rock with inconceivable swiftness and agility.

We need scarcely remind the reader of the very ancient subservience of this species to the domestic uses of mankind. It is the first recorded creature in the Holy Scriptures, of such as owned the dominion of the human race. "And Abel was a keeper of sheep, but Cain was a tiller of the ground."[5] Sheep-shearing is also mentioned during very early times: "And it was told Tamar, saying, Behold thy father-in-law goeth up to Timnath to shear his sheep;"[6] while, at a later period, the festivities of the season were taken advantage of by Absalom to slay his brother Amnon: "And it came to pass, after two full years, that Absalom had sheep-shearers in Baal-hazor, which is beside Ephraim; and Absalom invited all the king's sons."[7] The domestication of the sheep thus appears to have been almost coeval with the creation of our own species, and continuous with its progressive descent. We may here mention that the goat appears to be the next in succession, as applied to the purposes of the human race; then oxen, asses, camels, and lastly horses. The first mention of the mule, though prior to that of the horse, is of too casual a kind to lead to any precise conclusion, as to its being then known as a beast of burden: "And these are the children of Zibeon; both Ajah and Anah: this was that Anah that found the *mules* in the wilderness, as he fed the asses of Zibeon his father."[8]

The most remarkable external change which domestication has produced on sheep, is the conversion, as it is commonly called, of hair into wool, or, to state the fact more accurately, the prodigious development of one of the constituent portions of the coat, and the decrease or disappearance of the other. All animals inhabiting a cool or temperate climate seem supplied with both a woolly and a hairy covering,—the former being usually short and close, and entirely concealed by the latter, on the length, colour, and texture of which the external appearance of most animals in a great measure depends. These two kinds of covering are very observable in bears and wolves, and also in the more peaceful races of wild sheep; and nothing like either a metamorphosis or a new creation is necessary to produce the remarkable alteration in the domestic breeds. Of these we here figure as an example the long-legged sheep of Africa. (See Plate XV., figure 1.)

The principal unsubdued races of the sheep are the following: the Mouflon or Musmon of Sardinia, Crete, and Corsica (*Ovis musimon*, Pall., *O. ammon*, Gmelin, *O. aries*, Desm.),—the bearded sheep of Africa (*Ovis tragelaphus*, Cuv., Desm.),—the Argali, or wild sheep of Asia (*Ovis ammon*, Linn., Desm.), and the Rocky Mountain sheep of America (*Ovis montana*, Richardson). These four quadrupeds differ greatly, in the first place, in their geographical position; and, secondly, in several of their external characters. The distinctive attributes of all the species have not been detailed with sufficient fulness and precision to enable us to say with certainty whether each differs specifically from the other, or is rather its natural representative under a different modification of climatic influences. However this may be, it is probable that from one or other of these unsubdued races our own domestic tribes have been derived, and we shall therefore present the reader with a brief sketch of their natural history.

Ovis musimon, Pallas. The Musmon.[9] (See Plate XV., figure 4.) This species measures about three feet and a half in length, and its height, at the highest part of the back, is about two feet six inches. The neck is large, the body thick, muscular, and of a rounded form. The limbs are robust, and the hoofs short. The horns of the male are nearly two feet long. The body is protected by a short, fine, grey-coloured wool, of which the filaments are spirally twisted, and by a stiffish silky hair of no great length, yet sufficient to conceal the wool beneath. The Musmon (under which name it was known to the ancients) inhabits the loftiest parts of Crete, Corsica, and Sardinia, the western mountains of European Turkey, the isle of Cyprus, and probably other islands of the Grecian Archipelago. It is not, however, supposed to occur in more northern countries, unless the identity of the species with the Siberian Argali should in time be demonstrated. It is mentioned as an inhabitant of Spain by Pliny, and according to Bory St Vincent, it still occurs among the mountainous provinces of the ancient kingdom of Murcia. It is gregarious in a state of nature, and seldom descends from the highly elevated portions of its insular mountains, of which the elevation and latitude, however, do not admit perpetual snow. About the month of December or January, the larger troops divide into less numerous bands, each consisting of a male and a few females. For a short time after this period, when the males encounter each other, fierce battle ensues, and one of the combatants is not unfrequently slain. The females carry their young for five months, and usually produce twins in April.

[9] *Mouflon* of Buffon and F. Cuvier,—*Ovis aries* (race sauvage considérée comme le type primatif) of Desm.

We have said that the question is still undetermined regarding the origin of our domestic breeds. The prevailing sentiment, however, is certainly in favour of the species just named. We know that the Corsican musmon brought to Britain by General Paoli, became the parent of a mixed progeny; and if Pliny is to be regarded in the light of an authority, the wild sheep of Spain frequently intermingled with the domestic race. The produce were known by the name of *umbri*. We may observe that all wild sheep have the chaffron greatly arched, and this peculiar form of the nasal bones is found to increase with the degeneracy of the domestic breeds.[1] Colonel Hamilton Smith seems to suspect that even the musmon itself may not be a genuine wild animal, but an African domestic breed once imported, and partially restored to its primitive characters, by the security afforded by its insular situation after it had accidentally escaped from the influence of man.

Ovis tragelaphus, Cuv. The bearded sheep of Africa.[2] The hair on the lower part of the cheeks and upper jaws of this species is extremely long, and forms a double or divided beard. The hairs on the sides and body are short, those on the top of the neck somewhat longer, and rather erect. The whole under parts of the neck and shoulders are covered by coarse hair, not less than fourteen inches long; and beneath the hairs on every part there is a short genuine wool,—the rudiments of a fleecy clothing. The tail is very short. The horns approach each other at their base, and are above two feet long, about eleven inches in circumference at the thickest part, and diverge outwards, the extremities being nineteen inches from each other. The size of this animal is differently stated by different authors, and some confusion has arisen in its history and synonymy from the want of accordance between figures and descriptions. It inhabits the desert steeps of Barbary, and the mountainous parts of Egypt. The specimen in the Paris Museum was shot near Cairo.

Ovis ammon, Linn., Desm. The Argali or wild sheep of Asia. The general colour of this species is fulvous grey, and white beneath, with a whitish disk upon the buttock. The wool lies as it were concealed beneath a close set hair. The adult male measures about three feet in height at the shoulder, and five feet in length. His horns are nearly four feet long, and fourteen inches in circumference at the base. They are placed on the summit of the head, so as to cover the occiput, and nearly touch each other in front, bending backwards and laterally, then forwards and outwards, their base being triangular, and their surface wrinkled. The female is of smaller size, and her horns are nearly straight. This species seems to have been confounded by most writers of the earlier portion of last century with the mouflon, a European species already noticed; and even Pennant and Shaw, in compiling its history, have amalgamated the accounts of two distinct kinds. Gmelin (the traveller[3]) and Pallas[4] have furnished us with the most accurate as well as ample details of its actual characters. It inhabits the mountains of Central Asia, and the elevated Steppes of Siberia, from the banks of the Irtisch to Kamtschatka. In the last named country, its flesh and fat are much esteemed. The horns are sometimes so large as to admit of young foxes taking shelter in their decaying cavities. The name of Argali applied by Pallas to this species, is the Mongolic title of the female. The male is called Guldschah. It is the Weissarsch of the ancient Germans, and in more modern times appears to have been first noticed by Father Rubraquis in the thirteenth century. He calls it *Artak*, most likely an erroneous reading for *Kirtaka*, which, according to Hamilton Smith, is one of its Tartaric names.

Ovis montana, Desm., Rich. The Rocky Mountain sheep, or American Argali. (See Plate XV., figure 6.) This animal exceeds the Asiatic kind in size, and is larger than the largest varieties of our domestic breeds. The horns of the male are of great dimensions, arising a short way above the eyes, and occupying almost the entire space between the ears, but without touching each other at their bases. The horns of the female are much smaller, and but slightly curved. The hair in this species resembles that of a deer. It is short, fine, and flexible, in its autumn growth, but becomes coarse, dry, and brittle, as the winter advances. The colours reside in the ends of the hair, and as these are rubbed off during the progress of winter, the tints become paler. The old rams are almost entirely white in spring. The Rocky Mountain sheep inhabits that lofty and extended chain of North America from which it derives its name,—from its most northern point in latitude 68°, to at least the 40th degree. Its flesh is delicious, exceeding, it is said, in flavour that of the finest English mutton.

GENUS BOS, Linn. Incisives $\frac{0}{8}$, canines wanting, molars $\frac{6-6}{6-6}$; $= 32$. Body large, limbs robust, muzzle broad, the facial outline nearly straight. Horns simple, conical, lunate, directed laterally, the points raised. Tail rather long, and terminated by a tuft of lengthened hair. Four mammæ.

Buffon appears to have admitted of only two kinds of cattle—the bull and the buffalo. A wild bull, the source of our domestic breeds, the aurochs of Europe, the bison of America, and the zebu of Africa and Asia, were all regarded by him as varieties of one and the same species, produced by climate, food, and domestication. The humped backs of the bison and the zebu, according to the imaginative views of the eloquent Frenchman, were signs of slavery produced by grossness and excess of feeding; and he sought to escape the dilemma presented by the existence of wild cattle with humped backs, by at once asserting that these were either an emancipated tribe, originally descended from an enslaved and deteriorated race, or constituted in themselves a natural variety, of which the hump was characteristic. According to the same authority, it was a humped variety, which, passing from the north of Europe to the American continent, gave rise to the bison breed of that country,—a theory which he deems strongly confirmed by the fact, that both the aurochs of the Old World, and its representative in the New, smell strongly of musk![5] So confused, indeed, were his notions regarding these animals, that he appears to have confounded the bison and the musk ox, although Charlevoix, and other travellers to whom he had access, had previously described the difference in their external characters, as well as in their haunts and habits. He advances the northern boundaries of the bison almost to the Pole itself; whereas, in reality, it is only the musk ox that is found there: and then, forgetting what he had just before stated, he locates the race of aurochs in the Frigid Zone, and restricts the bison to the temperate,—while he draws the general conclusion that all domestic cattle without humps are descended from the former, and all humped cattle from the latter.[1]

[5] Bernard's *Buffon*, t. v. p. 100.

Though Pallas [2] refutes the mistake committed by Buffon in supposing that the aurochs of Europe consisted of two varieties—the urus and the bison—he himself falls into the equally gross error of confounding as identical the American and European species. He maintains the probability of the latter having passed from the Old World to the New, when the great northern continents were connected together by vast and continuous tracts of land, of which the shattered and sunken debris are still represented by the snow-covered mountains of Iceland, and the isles of Shetland and Feroe. He regards the aurochs as the original source of our domestic cattle, and both as synonymous with the bison of America,—while the musk ox of the New World, the grunting ox of the East, and the buffaloes of Asia and of Africa, are viewed as distinct from those just named, and from each other.

It thus appears that prior to the time of Cuvier the larger kinds of horned cattle were considered as amounting to *five* in number, so far as living species were concerned. But the great French anatomist speedily distinguished eight species.[3] He separated the aurochs from the bison, and established two additional kinds, the arnée of Asia, and the domestic bull, the source of which he traced not to the aurochs, of which the number of the ribs, the occipital arch, and the inter-orbital distances of the forehead, are dissimilar, but to a fossil species (probably by this time extinct in the living state), of which the bones occur in various alluvial soils of Europe. We shall here briefly notice the principal species of taurine animals.

Bos taurus, Plin. *Bos taurus, domesticus*, Linn. The domestic bull and cow. The most permanent and essential specific characters of this animal are the following: Forehead flat, higher than broad; horns round, placed at the two extremities of a projecting line, which separates the front from the occiput; ribs amounting to thirteen pair; teats disposed in the form of a square; hair of the anterior parts of the body not more bushy than that of the other portions. The original of this invaluable species is supposed to have been the *Urus* of ancient writers,—the *Thur* of the Polish nation, an animal which, from various accounts, appears to have borne a much closer resemblance to our domestic breeds, than do either the modern aurochs (commonly called the European bison) or the buffalo. It seems to have become almost extinct during the middle ages, in consequence of the progress of civilization among the western nations, and probably ceased to exist in a living state about the fifteenth century, except in a few of the royal forests of Poland. Herberstein and Martin Cromer state that the thur was to be found only in Massovia, near Warsaw, where it appears to have been kept as a curiosity, just as (according to Gilibert) the *zubr* or modern aurochs continues to be to this day. In the fossil skulls which seem to represent the urus, the horns are curved forwards and downwards; but in the countless varieties which constitute the domestic breed, these parts assume a great diversity of form and direction, and are sometimes altogether wanting. The ordinary races of the torrid zone (supposing the so called zebus to be descended from the same root) are generally distinguished by a hump or large excrescence of fat and flesh upon the shoulders.

We cannot here inquire, however briefly, into the history of our British cattle. The original introduction of "horned bestial" to our island, is neither known in history, nor asserted by tradition. Whether they were derived from abroad, or were descended from wild individuals of the urus race, native to Britain in former ages, are questions which the lapse of time will never solve, but rather tend to shroud in deeper darkness. The climate of the British Isles is, beyond most others, productive of a great variety in the nature of our pastures, and of a corresponding variety in the character and condition of such animals as depend on those pastures for support. Cæsar mentions the abundance of the British cattle, and adds, that we (that is the then inhabitants, for the present races, like the descendants of the animals in question, are a mingled breed) lived much on milk and flesh, to the neglect of tillage. Strabo praises our bountiful supply of milk, but denies to us the art of making cheese. This preference of a pastoral life over one of agriculture, was handed down to much more modern times, and prevailed throughout the continuance of our feudal government, the warlike services of which would have proved in a great measure incompatible with the prolonged and steady labours of tillage. In regard to the wild white cattle, commonly so called, which still exist at Chillingham Castle in Northumberland, at Wollaton in Nottingham, at Gisburne in Craven, at Chartly in Staffordshire, and at Hamilton in the county of Lanark, we shall merely mention that no sufficient evidence has ever been brought forward to prove that these are entitled to the character of an aboriginal breed. Fitz-Stephen, who lived in the twelfth century, speaks of the *uri sylvestres*, which in his time inhabited great forests in the neighbourhood of London, and at a later period (fourteenth century) King Robert Bruce was nearly slain by a wild bull, which attacked him "in the Great Caledon Wood," but from which he was rescued by an attendant, "whom he endowed," says Hollinshed, "with great possessions, and his lineage is to this day called of the Turnbulls, because he overturned the beast, and saved the King's life by such great prowess and manhood."[4] There is, however, a link wanting to connect these fierce creatures with the small and often hornless breed of white cattle still existing in the parks alluded to; and although the straightness in the backs of the latter animals, the fierceness of their dispositions, and their agreement in some particulars with the ancient unreclaimed breed of Britain, may afford a reasonable ground for conjecturing that they are identical with the primitive source of our domestic cattle; yet we are rather inclined to regard them as descended from the same source, than as constituting that source itself.

Bos urus, Gmelin, *Bos taurus*, var. *urus*, Linn. European Bison, or Aurochs of the Germans.[5] This species is frequently, though erroneously, regarded as the origin of our domestic cattle. "There is, I believe, no doubt," says Mr Bingley, "that the ox is a descendant of the bison, a large and powerful animal which inhabits the marshy forests and vales of Poland and Lithuania. In the lapse of many centuries, however, its general appearance, as well as its temperament and disposition, have undergone a radical change. The enormous strength of the body, the great depth of chest and shoulders, the shagginess and length of hair which covers the head, neck, and other fore-parts of the bison, as well as his savage and gloomy disposition, are in the present animal so altered that the mere variety would almost seem to constitute a distinct species."[1] This mistaken view of the subject has arisen from ignorance of the leading distinctive characters. The aurochs is distinguished by its bulged or convex forehead, which is, moreover, broader than high, by the attachment of the horns *below* the line of the occipital ridge, by an additional pair of ribs (fourteen instead of thirteen) by a sort of frizzled wool, which covers the head and neck, and forms a kind of beard or small mane upon the throat. The tone and utterance of its voice is also quite peculiar. It is a wild and independent animal, now confined to the marshy forests of Lithuania, of Carpathia, and the Caucasus, though formerly an inhabitant of the temperate parts of Europe. It is the largest of all the quadrupeds native to the European continent, measuring six feet in height at the shoulder, and betwixt ten and eleven feet in length, from the nose to the insertion of the tail. According to Gilibert, it far surpasses the largest of the Hungarian oxen. The horns are black, and thicker and more compact than those of the domestic bull. In both sexes the lips, gums, palate, and tongue, are blue, and the last named part is very rough and tuberculated. Certain portions of the hide have decidedly a musky smell, especially during the winter season; and the name of Bison is supposed to have been bestowed upon it in consequence of that peculiar odour,—from the German word *wisen* or *bisem*, which signifies musk. The name of Aurochs is probably synonymous with that of *Urus*, originally applied to another species.

[2] *Acta Petropolitana*, t. ii.

[3] *Diction. des Sciences Nat.* article *Bœuf*. The same amount of species (including the musk ox, *Ovibos moschatus*) is given in the last edition of the *Règne Animal*, but the *Arnée* of Asia is not there admitted as distinct.

[4] See a more detailed account in the *Cosmographe and Description of Albion*, prefixed to Bellenden's Translation of Boethius's *History and Chronicles of Scotland.* Tait's reprint, chap. x. p. 39.

[5] This is the *bison* of the ancients, the Bœuf aurochs of Desmarest. called *Zubr* by the Poles.

Bos bison, Linn. *Bos Americanus*, Gmelin. (Plate XV., figure 3.) The Bison of the New World, or buffalo of the Anglo-Americans. The head of this species resembles that of the preceding, and the anterior portions of its body are in like manner covered by a curled woolly hair, which becomes excessively long during the winter season; but its legs are shorter, its hinder extremities comparatively weaker, and its tail not nearly so long. It is said to have fifteen pair of ribs. It inhabits a great extent of territory throughout the temperate and northern parts of North America, and its history is so fully described by many modern authors, that we need not here dilate upon it.

Bos bubalus, Linn. The Buffalo properly so called. (Plate XV., figure 5.) The forehead of this animal is convex or bulging, higher than broad, the direction of the horns is lateral, and they are marked in front by a longitudinal projecting line. It is originally a native of India, from whence it was brought into Egypt and Greece. It was introduced into Italy about the close of the sixth century, and now grazes in numerous herds among the Pontine Marshes. Its milk is excellent, its hide extremely strong, its flesh but slightly esteemed.

Bos gavæus, Ham. Smith. *Bos frontalis*, Lambert. The *Gayal* of the Hindoos. Nearly of the size and form of the English bull, with a dull and heavy aspect, but in reality almost equalling the wild buffalo in activity and strength. Its horns are short, slightly compressed, thick though distant at the base, and rise directly outwards and upwards in a gentle curve. From the upper angles of the forehead proceed two thick, short, horizontal processes of bone, covered by a tuft of light coloured hair. There is no hump upon the back, but a sharp ridge runs along the hinder part of the neck and shoulders, and anterior portion of the dorsal region. This species inhabits the mountain forests to the east of Burrampootra, Silhet, and Chatgoon. The milk, though rich, is neither lasting nor abundant. The gayal has been domesticated in India, and is venerated by the Hindoos. The female has been known to produce with a common zebu bull of the Deswali breed.

Bos grunniens, Pallas. The Yack, or grunting ox,—*Soora Goy* of the Hindostanese. Occiput convex, and covered with frizzled hair; horns round, smooth, pointed, lateral, bending forwards and upwards; withers very high, but not so decidedly hunched as in the zebus; mammæ four, placed transversely; fourteen pair of ribs; hair on the neck and back woolly,—very long upon the tail. This species dwells among the mountainous regions of Central Asia, and produces the *horse-tails* (commonly so called), used as standards by the Turks and Persians. The *chowries*, or fly-drivers, made use of in India, are likewise formed from the tail of the grunting-ox. It is dyed red by the Chinese, and worn as a tuft to their summer bonnets.[2] The animal is domesticated by the Mongolians and by the Tartar tribes. Though not large boned, it looks bulky, owing to its long and ample coat of hair. It has a downcast heavy look, is sullen and suspicious, and usually exhibits considerable impatience on the near approach of strangers. It is sure-footed, and capable of carrying a great load as a beast of burden, but is not employed in agriculture.[3]

Bos Caffer, Sparmann. The Cape Buffalo,—*Qu'Araho* of the Hottentots. This species is characterized by dark rufous horns, spreading horizontally over the summit of the head, with the beams bent down laterally, and the points turned upwards. They measure from eight to ten inches broad at the base, and are divided from each other only by a slight groove. They are extremely heavy, cellular near the root, and measure five feet in extent, following the curved line from tip to tip. The hide of the Cape buffalo is black, and, especially in old animals, almost naked. Its tail bears a tuft of bristles at the end. It is a gregarious animal, dwelling in small herds in the brushwood and open forests of Caffraria, and striking accounts of its strength and ferocity are recorded in the writings of Sparmann and Thunberg. Like most of the genus, it is sometimes capable of being excited almost to madness by any thing of a red colour. It swims with surprising force and agility.

Bos moschatus, Gm. The Musk Ox,—*Ovibos moschatus*, De Blainville. This singular animal inhabits many districts of America to the north of the sixtieth parallel. We owe our first systematic knowledge of it to Pennant, who received a specimen of the skin from the traveller Hearne;[4] but it had been previously mentioned, though vaguely, by several of the early English voyagers, and M. Jeremic had imported a portion of its woolly covering into France, from which stockings more beautiful than those of silk were manufactured. When full-grown, the musk ox is about the size of our small Highland breed of cattle. Its carcass, exclusive of the offal, weighs about 300 pounds. Its flesh, when in good condition, is well flavoured, resembling that of the rein-deer, but coarser grained, and smelling strongly of musk. The horns are remarkably broad at their bases, and cover the brow and crown of the head, where they come in contact with each other. The nose is blunt, the muzzle not naked as usual, but covered with short close-set hairs, and the head is large and broad. The legs are naturally rather short, and this dumpy character is increased by the great length of the hair upon the body, which hangs down almost to the ground. The horns of the cow are smaller than those of the male, and do not touch each other at their bases, and the hair on her throat and chest is shorter. The musk ox spreads over a great extent of the barren arctic regions. It visits Melville Island (north lat. 75°) in the month of May, but does not, like the reindeer, extend to Greenland and Spitzbergen.

---

[2] Turner's *Account of an Embassy to Thibet*, p. 86, pl. 10.

[3] This species is no doubt the *Poephagus* of Ælian. It is curiously described in the old English translation of Conrad Gesner. See *The History of Four-footed Beasts and Serpents*, collected by Edward Topsel, 1658.

[4] *Arctic Zoology*, vol. i. p. 11.

Besides the eight species now enumerated, the Asiatic arnee (*Bos arnée*), and several other animals, either distinct in kind, or constituting well marked varieties of horned cattle, have been described both by travellers and systematic writers.[1]

The following is a summary of the geographical distribution of the principal species. Two are proper to North America,—the musk ox (*B. moschatus*), which dwells within the polar circle, and the bison (*B. Americanus*), which inhabits from that circle southwards, till between the 40° and 35° of north latitude. A like number is characteristic of Europe, viz. the aurochs or European bison (*B. bison*), called zubr by the Poles, and the genuine bull (*B. taurus*), the thur of the middle ages, and urus of the ancients, now extinct in the natural state. There are at least four species found in Asia,—the yak or grunting ox (*B. grunniens*), the common buffalo (*B. bubalus*), the arnee (*B. arnée*), and the gayal (*B. gavæus*). Only a single well-determined species inhabits Africa, the Cape buffalo (*B. caffer*). In relation, then, to the localities of species, it thus appears that the zone inhabited by the genus *Bos* stretches obliquely across all climates; and that each species, with the exception of the bull and buffalo, now reduced to universal slavery, and widely extended from their original centres through the dominating influence of man, is confined within certain circumscribed limits, in which it is retained as well by natural barriers as by instinctive inclination. The difference in the habits of life observable between the American and European bisons would of itself have sufficed to establish the specific distinction of these animals. Had they been identical, the aurochs or European species would have preserved in America that love of retirement which induces it to dwell in the central solitudes of forests, where (in that of Hercynia) it was found in the days of Cæsar, as it now is in those of Lithuania, or amid the loftier gloom of the Carpathian Mountains. The American bison, on the contrary, congregates in large troops, and delights to dwell in those open plains or prairies which produce a thick and abundant pasture. The musk ox, without avoiding such stinted forests as the sterile regions to which it is native are capable of producing, yet dwells for the greater portion of the year among the rocky and almost ice-covered mountains of the extremest north, "creating an appetite under the ribs of death," with, we fear, but little wherewithal to appease that appetite after it has been created. The buffalo (of Asiatic origin) is an animal of almost amphibious habits, fond of the long, coarse, rank pasture which springs up so speedily in moist and undrained lands. Hence its love of the Pontine marshes, where, according to Scaliger, it will lie for hours submerged almost to the muzzle,—an instinctive propensity which it is seen equally to exhibit in the Island of Timor. The yak inhabits elevated ranges, and the cool and lofty table lands of central Asia, while the buffalo of the Cape delights to dwell in the dense forests of Southern Africa. All these species, with the exception before named, may be regarded as the aboriginals of the countries where they now occur.[2]

ORDER VIII.—CETACEA, CUV.

We now come, finally, to the Cetacea, or whale tribe, which has usually been placed as the last in our systematic works; and very naturally, as these animals differ greatly from those of the preceding orders, in being inhabitants not of the land, but solely of the water; and though formed internally on the same general plan as quadrupeds, they have yet been adapted alike admirably and wonderfully, to all their exigencies as dwellers in the "great deep." The naturalist knows that their structure distinguishes them widely from the whole of the finny race (or fishes properly so called), and allies them closely to quadrupeds, and with these last, therefore, he associates them; whilst mankind in general, judging from their external appearance, allies, or rather identifies them with the class of fishes. Their marked peculiarities, then, arising chiefly from the adaptation of their structure to the watery element they inhabit, might well require from us more ample details than our nearly exhausted space will now allow. The great interest, however, as well as importance, of this branch of the subject, and the acquisition of materials recently derived from foreign sources, not yet available to the English reader, induce us to enter into some details. The scientific naturalist need scarcely be reminded of the extremely superficial manner in which this extraordinary order has hitherto been treated in all our compendiums of general knowledge.

The Cetacea are characterized as Mammalia without posterior extremities,—even the bones of the pelvis being scarcely represented by two small rudimentary ones, which hang suspended in the softer parts; the body is pisciform, with the tail cartilaginous and horizontal. The anterior extremities assume the appearance of fins, or swimming paws (as they have been more appropriately designated), having the bones flattened and short. They reside constantly in the water; but, as they breathe by lungs, they are obliged to ascend to the surface at frequent intervals for the purpose of respiration. Their blood is warm; they are viviparous; their mammæ are in some pectoral, though in most abdominal.

The Cetacea are arranged in two great divisions, viz. the *Herbivorous* and the *Ordinary* Cetacea.[3]

DIVISION I.—CETACEA HERBIVORA.

The *Herbivorous Cetacea* of Cuvier; also known as the *Sirenia*,—and popularly as *Tritons*, *Mermaids*, *Sea-cows*, &c.

The characters of this division are as follows:—Head not distinguished from the body by a neck; no blow-holes on the head, but nostrils on the snout; body pisciform; no dorsal fin; tail horizontal; pectoral fins resembling swimming paws; mammæ pectoral; skin nearly destitute of hairs; teeth very peculiar, but adapted only to a herbivorous regimen.

Until the present century the herbivorous Cetacea were intermingled with the seals or sea-dogs, and the walrus or sea-horse; but from these they are very decidedly distinguished by the total absence of every vestige of posterior extremities, so that the inferior half of the body is but little different from the ordinary Cetacea. From these latter again they differ in having no blow-holes on the summit of the head, but nostrils much resembling those of several quadrupeds. Although wholly aquatic, they do not, like the majority of the other Cete, feed upon fish, and hunt them through the wide ocean, but they live solely upon vegetables, and these such as are supplied by the shallows of the sea, its estuaries, and the banks of rivers. Hence it is, and also from a general resemblance in the upper parts of the body, that they have so generally received the names of sea-calves and sea-cows.

Desmoulins' *Memoire sur la Distribution geographique des Animaux Vertebrés, moins les Oiseaux*, in *Journal de Physique*, Fevr. 1822; Baron Cuvier's *Ossemens Fossiles*, t. iv. the article *Bœuf*, in the *Diction. Classique d'Hist. Nat.*; and Mr Wilson's third *Essay on Domestic Animals* in the *Quarterly Journal of Agriculture*, No. viii.

[3] We owe much to the excellent work of Camper, entitled, *Observations Anatomiques sur la Structure Interne et le Squelette de Cetacés*, with notes by Cuvier, 4to, Paris, 1820. The remarks of Dr Scoresby, in his various publications on the Arctic regions, have greatly enriched this branch of zoology. The *Histoire Naturelle* of Lacépède contains good remarks, but the plates are generally execrable.

There can be no doubt that these Cete, in most instances, formed the type of those ideal objects of ancient poetry, the tritons, half men and half fish, who had power to calm the stormy surge; and probably too of the sirens, those sea nymphs whose melody charmed the entranced voyager to his destruction and death. Without, however, dwelling on these well known figments, we shall, in a few words, state the more modern fancies, especially those of the northern races, regarding this peculiar group. "Beneath the depths of the ocean, an atmosphere exists adapted to the respiring organs of certain beings resembling, in form, the human race, who are possessed of surpassing beauty, of limited supernatural powers, and liable to the incident of death. They dwell in a wide territory of the globe far below the region of fishes, over which the sea, like the cloudy canopy of our sky, loftily rolls, and there they possess habitations constructed of the pearly and coralline productions of the ocean. Having lungs not adapted to a watery medium, but to the nature of atmospheric air, it would be impossible for them to pass through the volume of waters that intervenes between the submarine and the supramarine world, if it were not for the extraordinary power of entering the skin of some animal capable of existing in the sea. One shape that they put on, is that of an animal human above the waist, yet terminating below in the tail of a fish; and thus possessing an amphibious nature, they are enabled not only to exist in the ocean, but to land on the shores, where they frequently lighten themselves of their sea dress, resume their proper shape, and with much curiosity examine the nature of the upper world that belongs to the human race."[1]

A knowledge of the existence of such legends is almost necessary to account for the effects which have been usually produced by an encounter with these far-famed, but slightly known animals. We shall here adduce only a single relation of the supposed appearance of a merman, and another of his fair companion. Three sailors being in a boat, about a mile from the coast of Denmark, near Landscrone, observed "something like a dead body floating in the water, and rowed towards it. When they came within seven or eight fathoms, it still appeared as at first, for it had not stirred; but at that instant it sunk, and came up again almost immediately in the same place. Upon this, out of fear, they lay still, and then let the boat float, that they might the better examine the monster, which, by the help of the current, came nearer and nearer to them. He turned his face, and stared at the men, which gave them a good opportunity of examining him narrowly. He stood in the same place for seven or eight minutes, and was seen above the water breast-high: at last they grew apprehensive of some danger, and began to retire; upon which the monster blew up his cheeks, made a kind of roaring noise, and then dived from their view. In regard to his form they declare, in their affidavits, that he appeared like an old man, strong-limbed, and with broad shoulders; but his arms they could not see. His head was small in proportion to his body, and had short curled black hair, which did not reach below his ears; his eyes lay deep in his head. About the body, and downwards, the merman was quite pointed like a fish."[2] Again, in 1823, "The crew of a fishing-boat, when at the deep-sea fishing, above thirty miles from land, upon drawing their lines, were not a little surprised to find that they had hooked by the back of the neck, and brought alongside, an animal of a singular aspect. They mustered resolution enough to take it into the boat, and keep it for some time: but on perceiving its pectoral mammæ, and on seeing it gasp, certain superstitious fears as to its being unlucky to kill a mermaid prevailed, and in an evil moment they slipped it overboard. On hearing of the circumstance, Sir Arthur Nicolson of Lochend, a most intelligent Shetland proprietor, and justice of the peace, called the men, three in number, put them on oath, and took down their description of the animal. The animal seems to have been a female, the mammæ being described as prominent and full. The skin was smooth and slimy; light grey on the back, and pure white on the belly. The swimming-paws terminated in webbed fingers. The eyes were small and of a blue colour; the neck remarkably short. The length was estimated at more than three feet, the largest circumference about two feet and a half. From the middle, the body tapered rapidly towards the tail, which was horizontal, and of a semicircular shape."[3]

Some of these animals have a voice, which, in certain circumstances at least, is interesting. In proof of this we shall allude to an incident mentioned by Captain Colnett as having occurred in his voyage to the Pacific, off the coast of Chili. "When in latitude 24° south," he says, "a very singular circumstance happened, which, as it spread some alarm among my people, and awakened their superstitious apprehensions, I shall mention. About eight o'clock in the evening, an animal rose alongside the ship, and uttered such shrieks and tones of lamentation, so like those produced by the female human voice when expressing the deepest distress, as to occasion no small degree of alarm among those who first heard it. These cries continued for upwards of three hours, and seemed to increase as the ship sailed from it. I never heard any noise whatever that approached so near those sounds which proceed from the organs of utterance in the human species."[4] It is, of course, such occurrences as these that have given origin to the many poetical effusions which we so often hear conjoined with all the charms of song.

> "What fairy-like music steals over the sea,
> Entrancing the senses with charm'd melody,
> 'Tis the voice of the mermaid that floats o'er the main,
> As she mingles her song with the gondolier's strain."

But it is now time to leave the regions of fiction and of superstitious exaggeration, and to present a sober, and, so far as ascertained, a correct view of this interesting group. It is now divided into three genera, and about twice as many species. There is first the genus *Manatus*,—the manatee of the West Indies; then the *Halicore*, or Dugong of the East Indies; and, thirdly, the *Stellerus*, an inhabitant of the polar regions. Of each of these genera it is on good ground supposed, that there are several species, which, however, still remain to be demonstrated. Of the *Manatus* there are not above two or three living species accurately ascertained, and as many which belonged to a former era of the world's history. Of the *Dugong*, so highly prized in the Eastern World, only one species is correctly known, and this chiefly through the zeal and energy of the late Sir T. S. Raffles when Governor of Batavia. For our knowledge of the manatus we are mainly indebted to the Duke of Manchester, who held the corresponding station in Jamaica. Of the *Stellerus* also, a name derived from the indefatigable naturalist of the expedition of the celebrated Behring, only one ascertained species is known. But let us proceed to the details.

GENUS MANATUS, Cuv. *Trichechus*, Linn. The manatus, as its name implies, derives its principal generic character from its swimming paws. These, as in the other genera, are formed of soft parts and a membrane, which envelope the bones of the hands and fingers; but in the manatus four flat nails are also seen, which are attached to the edge of the fin. The tail is no less characteristic; it is long, extending to about one-fourth of the body, and oval-shaped, which gives the animal some resemblance to an otter.

The first species we notice is the *Man. Americanus* of Cuvier, Desmarest, &c. (See Plate XV., figure 1.) Head conical; no neck; muzzle large and fleshy, semicircular at its upper part, where are the nostrils; upper lip full and cleft in the middle; two tufts of stiff bristles are situated at its sides; lower lip much shorter; mouth not very large; skin of a greyish colour, with a few slender hairs scattered here and there; pectorals long, large, and oval, terminated by four flat nails. Length twenty feet. Vertebræ, according to Baron Cuvier, six (cervical), sixteen (dorsal), twenty-four (lumbar and caudal), in all forty-six. According to the late Sir E. Home, seven, seventeen, twenty-four, in all forty-eight. There is a corresponding difference between these authors as to the number of the ribs, which are peculiar, being almost round, and very large and thick. So also with the teeth, which, according to Cuvier, are $\frac{9-9}{9-9} = 36$; and to Home $\frac{6-6}{6-6} = 24$. Two incisives appear in the very young, but speedily drop out.[1]

Their manners and dispositions are stated by voyagers to be inoffensive, mild, and even amiable. Buffon states that they are both intelligent and sociable, not naturally afraid of man, but rather free to approach him, and to follow him with confidence and promptitude. But they have especially a kindly feeling for their fellows. They usually associate in troops, and crowd together with the young in the centre, as if to preserve them from all harm; and, when danger besets them, each is willing to bear his share in mutual defence or attack. When one has been struck with the harpoon, it has been noticed that the others will attempt to tear the dreadful weapon from the wounded flesh. When the cubs are captured, the mother becomes careless of her own preservation; and, should the mother be the victim, the young follow her fondly to the shore, where they are speedily secured and slain. Buffon also tells us that Gomara reared one in a lake in St Domingo, and preserved it for the long period of twenty-six years. It became so tame and familiar as to answer to its name, and took pleasantly whatever nourishment was offered.

The manatus is not found in deep waters. It frequents the shallow bays among the West Indian islands, and the sheltered creeks of the South American continent, particularly of Guiana and the Brazils. It was chiefly at the mouths of those vast rivers the Oronooko and the Amazons, "where ocean trembles for her green domain," that innumerable flocks of these cetacea were in use to dwell. They also ascended the fresh-waters for many hundred miles, entered many of their tributary streams, and peopled the interior lakes with their fantastic forms. The historian Binet has remarked, that, in his time, there were certain places within ten or twelve leagues of Cayenne where these creatures so abounded that a large boatful could be procured in a day; and, according to Barbot, the inhabitants of Cayenne were in the habit of sending brigantines to various localities to buy them from the Indians, who, for beads and toys, and iron tools, would fill their vessels. But the high estimation in which their flesh was generally held, and the avidity with which they were pursued, led ere long to a vast thinning of their numbers, in those countries which are thickly inhabited. They have retreated before the tide of population; and, wherever men are numerous, there they become scarce and shy, and, it is alleged, more fierce and vindictive in their disposition.

M. Senegalensis, Adanson, Cuv., Desm. This species, which frequents the rivers and shores of Western Africa, so much resembles the former in general appearance, and so little is explicitly known about its habits, that we shall merely adduce its characters. The bony cranium is somewhat shorter, in proportion to its breadth, than that of the preceding. Breadth of nasal foramina three-fourths of their length; the inferior margin of the lower jaw is curved, while it is straight in the *Americanus*. Length seldom more than eight feet. Dr Harlan published an account of what he considered another Manatus (he names it *latirostris*), the bones of which were found in great numbers on the banks of the rivers of the Floridas.[2] Cuvier discovered several fossil bones belonging to this genus, on which we do not now insist; and shall only further add, that the best informed naturalists suppose that several other living species still remain to be described.

GENUS HALICORE, Illiger, Cuvier, Desm. *Dugungus*, Lacép. There seems little doubt that of this genus also several species, inhabitants of the Eastern Seas, exist. It is a popular belief of the Malays that two species frequent their coasts; and M. Fr. Cuvier states, that there are considerable differences between the Malay varieties, and one which had been procured from the Philipines. It would appear also that an analogous animal is known on the coast of New Holland, which is supposed by MM. Quoy and Gaimard to differ from those of the Indian Archipelago;[3] and finally, a species which has been recently observed by Dr Ruppel in the Red Sea, does not agree with any of the preceding. But concerning all these species (with one exception), we have little, or rather no accurate information.

H. Indicus or *Dugong*, Desm.; *Trichechus Dugong*, Linn.; *Halicore dugong*, Cuv. As late as the year 1820, it was stated by Sir E. Home in the Royal Society, and correctly, that no specimen of the Dugong of full size had ever been seen by any one who was conversant with comparative anatomy. In the year above named Sir Everard read two papers upon it, and Sir Thomas S. Raffles transmitted an interesting memoir from Sumatra. About the same time Messrs Diard and Duvaucel sent both accounts and specimens to France, which brought it under the inspection of Baron Cuvier, who gave the result of his observations in his *Oss. Fossil.* t. v. p. 261. From these sources we supply the following description.

The head is small; the nostrils are situated in the summit of the upper jaw, where it makes a curvature downwards, and they penetrate in such a manner that the upper semilunar edge, pressing upon the lower surface, forms a perfect valve, which is shut when the animal is feeding at the bottom of the sea. The eye is very small, and is supplied with a third eyelid; the aperture of the ear is so minute that it is with difficulty perceived. The upper lip is large, forming a vertical kind of snout, like a short proboscis, which is studded over with a few bristles; the lower lip is much smaller, and the interior of the cheeks is covered with coarse hair. The skin is smooth and thick, and yields no oil, the colour bluish above and white underneath. The swimming-paws present no appearance of nails, but are somewhat verrucose on their anterior margin. The tail is broad, horizontal and crescent-shaped. The total length is twelve feet reaching to twenty when fully grown. The skull is remarkable for the very peculiar manner in which the anterior part of the upper jaw is bent downwards, almost at a right angle, so as to form a kind of beak; the lower jaw is truncated so as to correspond with the upper. These peculiarities are well seen in the skeleton, which on this and other accounts is worthy of examination. (See Plate XVI., figure 2.) The dental apparatus is very peculiar. Besides the incisors and molars, there are two great tusks in the upper jaw, which are scarcely covered by the lip. Concerning the true history of the teeth, there is still considerable discrepancy. It would appear that the first incisors soon fall out, and that the second set remain rudimentary, having their place supplied by an extremely firm horny-looking substance in both jaws. The number of molars varies from five or six in the young, to two in the old, and these do not drop out and disappear as in most other animals, but, on the contrary, those nearest the front are necessarily pushed forward, and when nearly worn away, are pushed out by those behind, as occurs in the elephant. The vertebræ are seven cervical, eighteen dorsal, and twenty-seven caudal, in all fifty-two; ribs eighteen pair.

[3] *Zoologie du Voyage de l'Uranie*.

"The greatest peculiarity," says Sir E. Home, "in the structure of this animal, is that of the ventricles of the heart being completely detached from one another. This is not met with in any other animal."[1] Though this last statement is not strictly true, yet the structure is so peculiar that we have copied the excellent representation of it which Sir E. supplied to the Royal Society. (See Plate XVI., figure 4.) This sketch will represent the form which is common to the Dugong and the Stellerus, as will presently be seen; and which, so far as we know, has not been observed in any other animals. The following considerations, supplied by Sir E., are also interesting. "The skeleton may be compared to a boat without a keel, with the bottom uppermost, so that in the sea the middle part of the back is the highest point in the water; and as the lungs are extended to a great length close to the spine, they make the animal buoyant, so that when no muscular exertion is made the body will naturally float in a horizontal position. When we consider that this is the only animal yet known (with its congeners) that browses at the bottom of the sea unsupported by four legs, we must admit it will require a particular mode of balancing its body over the weeds on which it feeds; and in this way the centre of the back forms a point of suspension, similar to the fulcrum of a pair of scales, and the jaws are bent to correspond with this formation."[2]

The food of the Dugong appears to consist exclusively of the fuci and submarine algæ, which it finds at the bottom of the inlets of the sea. It browses on these vegetables precisely as a cow in a meadow, rising every now and then to respire. Its flesh resembles young beef, and is very delicate and palatable.

The Ikan Dugong is considered by the Malays as a royal *fish*, and the king is entitled to all that are taken. The flesh is by them considered as superior to that of the buffalo or ox. They distinguish two varieties. The breasts of the adult females are said to be large. The affection of the mother for its young is strongly marked; and the Malays make frequent allusion to this animal as an example of maternal affection. When they succeed in taking the offspring they feel themselves certain of the mother. The young have a short sharp cry, which they frequently repeat, and it is said that they shed tears. These tears are carefully preserved by the common people as a charm, the possession of which is supposed to secure the affections of those to whom they are attached, in the same manner as they attract the mother to her young. This idea, says Sir T. S. Raffles, is at least as poetical, and certainly more natural, than the fable of the Siren's Song.[3]

The last genus of the Herbivorous Cetacea is that called STELLERUS. The only known species was met with in the Northern Pacific, and being regarded by Steller as a species of Manatus, it received the appellation of *Trichechus Manatus borealis*. Cuvier, however, soon perceived that it was necessary to distinguish it as a distinct and peculiar form.

Stellerus borealis, Cuv., Desm.; *Manatus*, Steller, Pennant; *Trichechus Manatus borealis*, Linn.; *Rytina*, Illiger. This is a huge animal, reaching to the length of 26 or 28 feet. The skin is black, like the bark of an old oak; the head is small, and of an elongated form, with white moustaches, four or five inches long; the nostrils are situate at the end of the snout; the swimming-paws are beneath the neck, and serve for grasping as well as locomotion; they are terminated by a callosity, and have no nails; the tail is very broad but not long; the eyes are small, and can be covered by a cartilaginous membrane, which forms a third eyelid; the mouth is small, and has no proper teeth, but is furnished with two considerable bony-looking, but really horny masses, in their nature approximating to whalebone, one in the upper, the other in the lower jaw, not implanted into the maxillaries, but adhering to them. The vertebræ are 6, 19, 35, = in all 60.

The skin of this extraordinary creature is ragged and knotty. In fact, according to Cuvier, the scarf-skin is a kind of bark composed of fibres or tubes closely packed, perpendicular to the skin. These fibres are implanted into the true skin by small bulbs, so that when the epidermis is pulled off, the skin is remarkably rough and almost shaggy. As may be supposed, it has no hairs upon it, for the fibres themselves are nothing less than the hairs soldered together, forming a kind of cuirass. In a word, the animal is completely clad in a substance similar to the hoof of cattle. This hide is an inch thick, and so hard as scarcely to be cut with an axe; and when cut, it appears in the inside like ebony. This skin is of singular use to the animal during the winter, in protecting it against the ice, among which it feeds, and the sharp-pointed rocks, against which it is often dashed by the dreary tempest; and, during summer, in screening it from the rays of the never setting sun. The lips are double, that is to say, there are external and internal lips; and when approximated the space they circumscribe is filled by a thick mass of strong bristles, which are white, and an inch and a half long. These bristles in their nature, and still more in their function, agree with the baleen of the whalebone whales, serving as a sieve through which they can strain the water in which they feed, whilst they retain the food itself. The masticating apparatus is not less singular, and seems peculiar to this animal. It is not composed of teeth (of which we have already said there are none), but of two large white horny substances, forming dental masses, one of which adheres to the upper, and the other to the lower jaw. Even their insertion is peculiar, for they are not implanted into the bones beneath, after the manner of teeth, but only adhere to them by numerous pores and rugosities, corresponding to other projections and cavities in these bones. The substance itself has lately been discovered to be wholly horny, or composed of fibres agglutinated to each other, like the horn of the rhinoceros, and, when examined by the microscope, it is seen to consist of tubes. This structure is so singular that we have exhibited on Plate XVI., figure 3, the so styled tooth. A is the tooth itself, and *a*, *b*, *c*, *d*, *e* are the fibres or hairs, variously magnified, and viewed horizontally and vertically. These investigations have been made by M. Brandt, from a preparation in the Petersburgh Museum, and they are narrated in the Memoirs of its Academy, sixth series, vol. ii. But we must conclude these interesting details by Steller's account of the heart. This organ does not taper from the base to the apex, there to terminate in a single point, but it ends in two distinct and separate apices, corresponding to the two ventricles; the separation reaches to about one-third of their extent, at which place they unite, and then assume the usual appearance exhibited by the organ.

---

[1] *Phil. Trans.* 1820, p. 319.

[2] *Ibid.* 1821, p. 269.

[3] The Dugong of the Red Sea was observed by MM. Hemprich and Ehrenberg, but we owe its more detailed description to Edward Ruppel—(*Museum Senckenbergianum*, t. i. tab. 6). He deems it different from that of the Indian Seas, and has named it *Halicore tabernaculus*, in consequence of his historical researches having led him to the conclusion, that it was with the skin of this species that the Jews of old were compelled by the Mosaic law to veil their tabernacle. The Hebrews named it *Thaachasch*. The Arabians still esteem it for its flesh, its teeth, and skin, and name it *Naqua el baher*. There can be little doubt that the strange *fish* described by Forskal under the name of *Naqua*, was in truth this very dugong.—(*Descrip. Animalium, &c. quæ in itinere orientali observavit*). Ruppel observed it swimming among the coral banks which border the Dalac Isles on the coast of Abyssinia, between the 15° and 16° South Lat. The fishermen call it *Dauila*. They harpooned a female ten feet long, which our traveller dissected and described. He was further informed by the Arabs, that these Dugongs live in pairs or small families; that their voices are very feeble; that they feed on algæ; and that, in the months of February and March, bloody combats take place among the males. The females produce in November and December. The former sex attains to the length of eighteen feet,—the latter never equals that extent. We may add that M. Sommering (merely, however, from a comparison of the writings of Home with those of Ruppel), doubts the fact that the supposed species of the Red Sea is specifically distinct from that of the Indian Archipelago.

The *Stellers* are most voracious creatures, and feed with their heads under water, quite inattentive to boats or whatever else may be passing around them. They swim gently one after another, sometimes with a great portion of the back out of the water, and every now and then they elevate their muzzles for the sake of respiration, making a noise like the snorting of a troop of horses. They were captured at Behring's Island by a great hook fastened to a long rope. This was taken into a boat, which was rowed amidst the herd. When struck into the animal, the rope was conveyed on shore, where about thirty people took hold, and drew it on shore with great difficulty. The poor creatures made the strongest resistance, assisted by their faithful and attached companions, and they clung to the rocks with the greatest pertinacity.[1]

DIVISION II.—ORDINARY CETACEA.

In passing from the herbivorous to the ordinary Cetacea, we may remark, that the former take the precedence in our systematic works, not from their superior importance but merely because they approximate more closely to those Mammalia which dwell upon the surface of the earth, and thus link more continuously with our preceding orders. This remark applies with equal force to the sequence in which the more pisciform Cete are discussed. We are in the habit of commencing not with those which are the most imposing of the Order, and the most important in an economical or national point of view, but with those which approach the nearest to the division we have left; and this mode of progression, it must be admitted, possesses an interest peculiarly its own. We begin, accordingly, with the lower and more insignificant links of the scale, and gradually ascend till we reach the great monarch of the deep, which, as to dimensions at least, is the great monarch also of creation.

SUBDIVISION I.—DELPHINIÆ. Head of ordinary proportion, with numerous teeth. Blow-hole single.

A. those which have a dorsal fin.

This subdivision comprehends a very great number of species and even genera, which it has been found necessary to distinguish from each other. Baron Cuvier threw out the idea of employing the facial line in their arrangement, and this view has been further extended by M. de Blainville. We regard the suggestion as valuable and convenient, and shall therefore adopt it. Five distinctive variations of the line alluded to have already been selected as useful in the classification of these lesser Cete. These we have sketched on Plate XVI., at figures 6, 7, 8, 9, 10; to which we shall have occasion subsequently to refer.

GENUS (*a.*)[2] INIA, D'Orbigny. The beak is long like that of the dolphin, but cylindrical, and bristled with strong hairs; it has many teeth, incisives anteriorly, molars posteriorly. The temporal fossa and crest are also peculiar.

There is but one known species in the genus, the *I. Boliviensis*, D'Orbigny and Fred. Cuv. (See Plate XVI., fig. 11.) It is to the first named of these eminent naturalists that we are indebted for our acquaintance with this curious animal (very properly made by him to constitute a new genus), which establishes a link between the *Stellerus* and the *Soosoo*. This last frequents the Ganges, an hundred miles from the ocean; but the *I. Boliviensis* is met with thousands of miles from the sea, and is an inhabitant solely of rivers and fresh-water lakes. It is the only species of the whale tribe characterized by such peculiar localities. M. D'Orbigny found it in the early tributaries of the Amazons, 2100 miles from the ocean, at the foot of the Eastern Cordilleras, and was not a little astonished at his discovery. We must condense his description into the following formulary: Snout resembling a prolonged and very slender beak, almost cylindrical, obtuse at the point, and bristled with long strong coarse hair; the commissure of the lips reaching very far back, so as to be over the pectorals; pectorals very far forward, broad, long, and obtuse; dorsal-fin very low, two-thirds down the back; tail large, length 12 or 14 feet. Colour usually pale-blue above, passing into a rosy hue beneath; the tail and fins are bluish. Teeth $\frac{34 - 34}{33 - 33}$, $= 134$; many of them marked with deep and interrupted grooves. The auditory opening is larger than in most of its congeners; and we are not aware that the bristles on the beak have been seen in any of the other Cetacea. The appearance of the teeth is singular; they resemble incisors anteriorly, and posteriorly have an irregular mammary shape. This peculiarity, illustrated on Plate XVI., figure 5, somewhat approximates the *Boliviensis* to the herbivorous Cete, which it also resembles in its brilliant colouring.

This Inia comes more frequently to the surface of the water than its marine congeners, and appears less remarkable for agility and power. It habitually unites in little troops of three or four individuals, which are observed to raise their snouts from the water whilst devouring their prey, which appears to consist entirely of fish. In Bolivia they are hunted for their oil.[3]

GENUS (*b.*) SOOSOO, Lesson. The bony frame-work, more than any other part, forms the peculiarity of this genus, especially the long symphysis, and the great maxillary crests which rise above the walls of the spiracles. Besides, there is no furrow between the head and beak; the latter is very long, and slender, compressed at the sides, and expanded towards the extremity, so that it is broader at this part than in the middle.

---

[1] See Steller's valuable paper *De Bestiis Mar.* in *Nov. Comment. Acad. Petrop.*, t. ii. p. 294.

[2] The Arabic figures which we have made to precede the generic names of this extensive subdivision relate to the abstract exhibited at page 229, and which we hope will render our arrangement more perspicuous.

[3] See *Nouv. Ann. du Mus.* t. iii.

S. Gangeticus, Less.; *Delphinus Gangeticus*, Lebeck, Roxburgh;[1] *Platanista Gangeticus*, Fr. Cuv. (See Plate XVI., figure 13.) Of all the beaked dolphins, says the Baron Cuvier, the most extraordinary, and that perhaps which most merits being formed into a distinct genus, is the *Soosoo* of the Ganges. Lesson accordingly formed it into a genus distinguished by the name under which the only established species is known to the natives of Bengal. Cuvier thinks it is probably the *Platanista* of Pliny. The osteology of the cranium, he states, approximates it to the sperm whales.

The length is about twelve feet; the head is obtuse, suddenly tapering to a long and slender, but very strong beak; the jaws are nearly equal, amounting to about one-sixth of the length of the whole animal. The pectorals are of an oblique fan-shape; there is no distinct dorsal fin, but an angular projection nearer the tail than the snout. The colour is a shining pearly white. Teeth $\frac{30-30}{30-30}, = 120$. Spiracle linear, of the shape of an *ſ*, running backwards. Vertebræ, cervical 7, dorsal 11 or 12, lumbar 28. We may add that the form of the spiracle is unlike that of most of the lesser Cete, and corresponds with that of the Cachalot, or sperm whale. The tail is curiously festooned, and the pectoral fin scalloped. The eyes are stated to be exceedingly minute, only about a line in diameter, and of a bright shining black colour.

The Soosoos, says Dr Roxburgh, are found in great numbers in the Ganges, even so far up as it is navigable, but seem to delight most in the slow moving labyrinth of rivers and creeks, which intersect the Delta of that river, to the south and east of Calcutta. When in pursuit of the fish on which it feeds, it moves with great activity and uncommon swiftness, but at all other times, so far as noticed by the last named naturalist, its motions are slow and heavy; and it often rises to the surface to breathe. Between the skin and flesh is a coat of pale-coloured fat, more or less thick, on which the Hindoos set a high value, as a remedy of great efficacy in external pains. The flesh resembles lean beef, but is never eaten by the natives. Though this is the only known living species, it may be mentioned that Baron Cuvier has established the existence of several fossil kinds.

We must now take our leave of those smaller Cetacea which frequent only the shallow bays of the sea coast, browsing upon marine vegetation, or inhabiting "the rivers of water," to follow the far more numerous groups which revel throughout the vast depths of the unbounded ocean. The haunts of many of these are of course less known; and the facilities of capturing, and more especially of scientifically examining them, are greatly diminished. No wonder, then, need be excited by the avowal that a deep veil of obscurity lies over the history of the great majority, which all the bygone assiduity that has been exercised has as yet but partially removed. Our best endeavours will here be used to present the reader with whatever authentic information the accumulated efforts of naturalists have hitherto supplied, although, in the present embroiled condition of the subject, we cannot ensure ourselves against the chance of error.

Genus (*c.*) Delphinorhyncus. Snout prolonged, with a beak not distinguishable from the forehead by a furrow, or in other words, with the facial line almost continuous to the extremity of the muzzle. (See Plate XVI., figure 7.) A dorsal fin.

It was M. De Blainville who introduced this generic division, and it has been adopted by Desmarest, the Baron Cuvier and his brother, M. Lesson, and others. Though the distinguishing characters are sufficiently precise, yet, from the recent introduction of the generic term, and still more from our want of knowledge of the species, most of which have been only partially described, there is much doubt as to the ascertained number comprehended in the genus. Desmarest enumerated four, Lesson five, and M. F. Cuvier in his *Cetacés* only three. One of the last named author's species (*D. micropterus*) we reject, because it had many years before his proposed arrangement, been elsewhere and more accurately placed. His other two correspond with two of M. Lesson's. But of the five described by M. L., we must reject his *Malayanus*, because it possesses the characters of the genus Delphinus. Another of these species (*D. maculatus*) must be received with hesitation, because it has never been captured, nor of course examined, though observed with care from a vessel's deck. To these four of M. Lesson we shall now direct our attention.

D. Bredanensis, Less.; *D. rostratus*, Cuv.,[2] Fr. Cuv. (in his Mem.);[3] *Delphinus rostratus*, Cuv.,[4] Desm.;[5] *D. à bec mince*, Desm., Fr. Cuv., Less. (See Plate XVI., figure 14.) In this species, as in the rest of the genus, the profile of the cranium loses itself insensibly in that of the beak. Length of the only specimen examined eight feet; dorsal fin rising nearly from the middle of the back; pectorals falciform; colour sooty-black above, rose-colour beneath. Teeth $\frac{21-21}{21-21}; = 84$. As frequently happens, the osteology, and especially that of the cranium, has been known longer, and more accurately, than any other part of the animal. The city of Brest supplied some crania for the investigation of Baron Cuvier, as did M. Van Breda, Professor of Natural History at Gand; and accurate drawings of an individual thrown ashore on the coast of France, reached Paris, and removed all doubts as to its peculiar features. The colouring, we may remark, is singularly beautiful. All the upper parts are of a deep sooty-black, and the lower of a rich rosy hue. These portions are not separated by a distinct and uniform line; on the contrary, their junction is quite irregular, and many small black patches are figured upon the fairer colour. This species would appear to be an inhabitant of the Atlantic; but we believe it has not been seen alive, and we are not aware that any more information has been obtained regarding it than what has now been stated.

D. coronatus, Desm., Cuv.,[6] Less., Fr. Cuv.; *Delphinus coronatus*, Frémenville. Head small; forehead convex, obtuse; jaws prolonged into a pointed beak, the lower the largest. Teeth $\frac{15-15}{22-22}$, pointed and acute; general form elongated; dorsal fin nearer the tail than the head; pectorals of moderate size; tail crescent-shaped; length from 30 to 36 feet; colour a uniform black, but having two yellow concentric circles placed on the forehead,—the larger three inches diameter, the smaller about two. Hence its specific appellation. On the authority of the preceding noted names, we rank this very interesting species as a Delphinorhyncus, though we cannot dismiss all doubts upon the subject. Our knowledge of its existence rests solely, strange to say, upon the authority of M. De Frémenville, a distinguished naturalist, and officer of marine, who commanded an expedition towards the North Pole in 1806, chiefly for the purpose of geographical investigation. All subsequent accounts have been derived from that author.[7] He remarks that the only kind of whale he can describe with confidence, is a species which appears to have been previously unobserved. After supplying the description of its external characters, he adds, " the *coronatus* is common in the Polar Seas. I first met with it about 74° N., but it is chiefly between 77° and 80°, among the ice-islands near Spitzbergen, that it is found in numerous troops. Frequently during calms we were quite surrounded by it. These animals were so little shy that the water which they spouted fell on the deck. Their spouting was attended by considerable noise, and was effected with such force, that the water was immediately dispersed, and had the appearance only of a slight vapour; the jet itself did not rise above six feet."

D. Geoffroyi ?, Desm., Less.; *Delphinus Geoffroyi*, Blainv.; *D. frontalis*, Cuv. and F. Cuv. The fall of the frontal convexity is rapid; the beak marked and compressed; the specimen in Paris measured seven feet; the beak about ten inches; the horns of the spiracle are pointed backwards; the dorsal-fin very low; the pectorals well developed, and inserted low in the side. The specimen is painted grey on the back, white on the belly and round the eyes, the fins rosy-white. These are thought to be the colours of the living animal. The only specimen now known was brought from the Museum of Natural History of Lisbon to Paris by M. Geoffroy, in 1810. The colours indicated cannot with certainty be depended upon. It is supposed to have been brought from the Brazils.

D. maculatus ?, Less.; *Delphinus maculatus*, Fr. Cuv. Head slender, terminated by a long beak; body elongated, reaching to about six feet; dorsal fin placed in the middle; tail large. The colour in the water appeared a bright green, but out of it, the tint of the back was azure, of the belly grey, dappled with round spots bordered with red; the edges of the jaws, and especially of the upper one, were pure white. This species was seen, but not captured, in 18° S. and 137° W.

In advancing from the recently established genus DELPHINORHYNCUS to that which is the oldest, perhaps, of any, viz. DELPHINUS, we wish we could inform our readers that we leave a region of hesitation and doubt for one of certainty and precision. This, however, is not the case; and the cause is evidently to be found in the many and great difficulties by which the subject is encompassed. These animals, residing in haunts so different from those frequented by man, are but rarely encountered, and when met with, are seen under circumstances in which examination is difficult, and capture almost impracticable; for they pass us by, and vanish, almost like the vessel's track upon the rolling waves. It is only then, by some very fortuitous circumstance, or by great and peculiar labour, that when seen they are secured,—and the chances are still more remote of their being rendered available to the advancement of science. But instead of dilating upon these difficulties, we shall simply state a striking proof of their magnitude. In 1822 Desmarest enumerated sixty-two species as belonging to the whale order; but he considered no fewer than twenty-nine of them doubtful and not established; and Lesson, in 1828, out of eighty-four species which he classified, could vouch for the accuracy and existence of not more than fifty. With regard, again, to the genus now before us, M. Fred. Cuvier, in his history of the Cetacea, published in 1836, while he regards sixteen species of proper dolphins as pretty well ascertained, describes seventeen, the existence of which is still doubtful. Linnæus had three species in his genus Delphinus; the number has now been multiplied more than tenfold. The greatest discrimination, however, is required; for, while some are to be regarded as unquestionably established, and others rest upon a high probability, or it may be, on a very low one, yet even the slightest notice may be valuable, and should not be lost to science. On the other hand, there are instances in which species which were at first erroneously admitted, have long passed current as established in the records of Cetology, and some of these can scarcely be excluded without a reason being assigned for doing so. As the authors we have named indicated the different degrees of probability on which the species rest, we shall follow their example, and shall distinguish, 1st, Those which appear to be established; 2dly, Those which are probable, though not free from doubt; and, 3dly, Those which are not only doubtful, but highly questionable.

GENUS (*d.*) DELPHINUS, Cuv., Desm., Blain., Less., Fr. Cuv., Gray. Forehead convex; snout in the form of a beak, and distinguished from the forehead by a marked furrow. (See Plate XVI., figure 8.)

D. Delphis, Linn., Bon., Lacépède, Desm., Cuv., &c., popularly, *Oie de Mer*, or Dolphin. (See Plate XVI., fig. 12.) This animal is perhaps more generally known through the fictions of ancient poetry, than by its soberer name of *goose of the sea.* It is universally considered as the dolphin of antiquity, or at least as the only actual origin of that fabled being, though assuredly unendowed with those extraordinary attributes and charms with which it has been so fancifully clothed. It is the *Hieros Ichthys*, or sacred fish of the heroic Greeks, and was awarded divine honours by that imaginative people. It was more particularly sacred to their god Apollo; the reason assigned for which is this,—that when Apollo appeared to the Cretans, and obliged them to settle on the coast of Delphis, where he founded that oracle so famous throughout antiquity, he did so under the form of a dolphin. Apollo was thus, according to Visconti, adored not only in connection with the Delphine province, but with the Delphinus fish. He was worshipped at Delphi, with dolphins for his symbols. The ancients respected the dolphin as a benefactor of mankind; they cherished the tale of Phalanthus, the founder of Tarentum, being carried ashore by a dolphin when wrecked on the coast of Italy; and fondly believed in the story of the musician Arion, who, when about to be thrown overboard by the sailors that they might appropriate his wealth, begged that he might be permitted to play some melodious tune, and then throwing himself into the sea, was received by one of the many dolphins which had been attracted by his music, and carried on its back in safety to Tænarus. It is also recorded, that the shield of Ulysses bore an image of the dolphin, and it is certainly found on very ancient coins and medals. It early appeared on the shield of some of the princes of France; and gave a name to a fair province of that empire, and hence a title to the heir-apparent of the crown.

Scarcely less fabulous are those other narratives which have been transmitted on the testimony of early naturalists. They tell us that the dolphin made itself familiar with man, and conceived a warm attachment for him. Pliny narrates that in Barbara, near the town of Hippo, a dolphin used to frequent the shore, and accept of food from any hand which supplied it; it would mix among those who were bathing, would allow them to mount its back, would consign itself with docility to their direction, and obey them with as much celerity as precision.[1] Still more extraordinary is that other tale narrated to illustrate the assertion that the dolphin is more partial to children than to adults. Thus, according to Pliny, it was recorded in several chronicles that a dolphin which had penetrated the Lake of Lucrinus, in Campania, every day received bread from the hand of a child, answered to his call, and transported him to the other side of the lake, on its back, to school. This intimacy continued for several years, when the boy dying, the affectionate dolphin, overwhelmed with grief, sunk under its bereavement. But with such stories as these, which might easily be multiplied from Herodotus, Plutarch, and other ancients, we shall not further tax our readers.

---

[1] Lib. ix. c. 48.

The common dolphin (*D. delphis*) is usually five or six feet long, but sometimes measures eight or nine. For its general appearance we refer to our representation in lieu of many details. (See Plate XVI., figure 12.) The tints, though not gay, are attractive. It is black on the back, and white underneath, with a peculiar glistening when in, or newly taken from, the water. It may be well, however, to remark, that "the dolphin, with its many dying hues," as mentioned in many books, and sung by modern poets, is not this creature, but another of a different nature, belonging even to a separate great division of the animal kingdom. It is a true fish, the beautifully coloured *Coryphæna Hippuris*, the Dorado of the Portuguese, and it would be well if its popular name (involving as it does a double application) were entirely dropped. The eyes of the common dolphin are small and supplied with eyelids: the pupil is in the form of a heart. Mr Rapp has minutely described the lachrymal gland, the peculiarities of which Mr Hunter, indeed, had previously pointed out. There is no olfactory nerve, nor ethmoidal foramina. The meatus auditorius is apparent, though very small. The jaws are equal; teeth $\frac{47-47}{47-47}$, = 188, pointed, slender, and somewhat curved, at equal distances from each other, and locking together when the mouth is closed. There are seven cervical, twelve dorsal, and fifty-two other vertebræ. Finally, the brain of the dolphin is very large, and developed to an extent which is quite extraordinary among the lower animals. Its weight, in relation to that of the whole body, has been stated as one to twenty-five, which is the same as that in man. The average of four accounts given in Cuvier's comparative anatomy is one-fiftieth of the whole; and Tiedemann, the highest modern authority in this department, remarks, "that the brain of the dolphin, next to that of the orang-outang, approaches nearest, in respect of size, to the human brain." This would lead to the supposition that its intelligence and mental capacity are considerable, and any indications which have been noticed are favourable to such opinion.

Few if any of the order appear to be more voracious than the dolphins. They live upon medusæ and fishes, especially upon flat fish, and cod, mullets, pilchards, and herrings. It used to be held that the common dolphin was an inhabitant of every sea throughout the world. This appeared the more credible, since the strength of the animal, and the velocity of its swimming, exceeding that of a ship in full sail, would readily account for its appearance in all seas, and even at the opposite poles.[1] A very different opinion, however, is now gaining ground, confirmatory of a sentiment of Buffon's in relation to land animals, more than once alluded to in the preceding portion of the present treatise, viz. that every distinct species has a characteristic and, with few exceptions, circumscribed locality. It is more difficult, of course, to ascertain the truth of this proposition, as it regards the inhabitants of the water, although many facts would seem to establish its truth with regard to the cetaceous tribes. The species now under review frequents the European seas, the Atlantic, and the Mediterranean; and other species of the genus occur in the seas of Africa, Asia, and America. They navigate the waters of the ocean in more or less numerous troops, and their strange gambols and rapid natation, which are daily observed by voyagers (with sometimes little else within their range of vision), has long made them famous. The common dolphin is peculiarly signalized by these qualities, which, however, it enjoys only in common with the majority of its congeners. To swim with the rapidity of an arrow, to shoot ahead of vessels which are scudding before the breeze, to spring out of the water and over the waves, are qualifications possessed alike by all the smaller Cetacea which live in the ocean.

The one we shall next allude to is almost the most perplexed of the genus. It is the

D. Tursio, Fab. 31, Bon., Desm. 761, Cuv., Less.; *D. Nesnarnak* of the Greenlanders, Fab., Bon., Lacép., Fr. Cuv.; *D. Oudre*, Belon, &c.; *Grand Souffluer* and *Great Dolphin* of the French; *Capidoglio* of the Italians, and Risso; *Bottle-nosed Whale*, Hunter, Plate 18, which he confounded with *D. Delphis*. *D. Orca?* Linn., Desm. 765. Head and beak of the genus; the lower jaw somewhat longer, and having a slight bend upwards; dorsal near the middle; pectorals oblong, pointed. Length stated from ten to twenty-four feet. Colour black above, whitish beneath, merging into each other on the sides. Vertebræ (six), seven, seventeen, twenty-seven = sixty (Hunter). Teeth $\frac{23-23}{21-21}$; of one form, straight, cylindrical, and blunt at the summit. Inhabits Northern Seas, Atlantic, and Mediterranean. The account of the "History of the natural history" of this species, would lead us into a very intricate and not very profitable discussion.

D. Nesarnak?[2] Cuv.[3] Desm. 762. The principal alleged difference dwelt upon by these eminent men is the number and arrangement of the teeth. We are disposed wholly to reject this as a distinct species.

D. Boryi, Desm. 757, Desmoulins,[4] Less., Fr. Cuv. Beak longish, much compressed, and very broad near the head, which is rather elevated; dorsal in the centre; length about eight feet. Colour mouse-grey above, bright grey beneath, and there striped with light blue. Known at once by a band of ivory-white on the sides of the head, very distinct from the grey underneath it.

Twice seen, near Madagascar, by Col. Bory de St Vincent, a learned and zealous naturalist, who communicated the particulars to Desmarest. On being captured the blue stripes underneath speedily disappeared.

D. frontalis, Dussumier, Cuv.;[5] *D. dubius*, Fr. Cuv. Head and beak of the genus; length of the specimen examined four and a half feet; dorsal somewhat behind the middle; pectorals attached one-fourth of the distance of the whole length from the anterior extremity, and one-sixth of the whole length, pointed. All the upper part of the body, sides, and tail a deep black; belly white, with a leaden-coloured streak running from the angle of the mouth to the base of the pectorals, which are quite black. Teeth about $\frac{36-36}{36-36} = 144$.

This species was captured by M. Dussumier near the Cape-de-Verd Islands. M. F. Cuvier has identified it in his Mammifères, and Cetacés with the *Dubius*; but so did not the Baron, nor do we think sufficient reason has been assigned for the step.

D. Pernettyi, Pernetty,[6] Desm. No. 756, F. Cuv. Re-

---

[1] Quoy les a vus souvent, dans le voyage de l'Uranie, précéder la frégate filant de neuf à onze nœuds par heure, comme on voit les chiens danois précéder les équipages dans les rues et les promenades publiques. On voit ainsi deux, trois, ou quatre Dauphins, quelquefois un tout seul s'exercer à lutter de vitesse, et par leurs zig-zags entrecroisés sous la pointe du beau-pré (et cela pendant des journées antiéres), faire quatre ou cinq fois plus de route que le vaisseau qui file de quatre à cinq lieues par heure."—*Diction. Classique d'Hist. Nat.*, t. v. p. 350.

[2] Wherever the mark of interrogation (?) follows the name of a species, we mean it to be understood that the existence of that species is extremely doubtful.

[6] *Voy. aux Malouines.*

Cetacea.

garded as a variety of the *Delphis* by Bonnaterre and Baron Cuvier. Head and beak of the genus; lower jaw somewhat longer than the upper; dorsal pointed, and placed behind the middle; colour black above, pearly grey below, and mottled with dark spots; teeth acute, and somewhat like those of the pike.

The vessel of Bougainville, in which Pernetty sailed, when near the Cape-de-Verd Islands was surrounded by about 100 of these dolphins, which approached very near it. They appeared, says Pernetty, to have come only for the purpose of diverting us; they made extraordinary leaps out of the water, some of them vaulting four feet high, and turning over two or three times in the air. The one taken weighed 100 pounds. To the common characters, which we have specified, Pernetty adds another, which we believe may be referred to many of the order, viz. that it exhaled an odour which was so strong and penetrating, that whatever substance was once impregnated with it, retained it for many days, in spite of all that could be done to overcome it.

D. Malayanus, Cuv.,[1] F. Cuv.; *Delphinorhyncus malayanus*, Lesson and Garnot. Head large, forehead convex, falling suddenly, and presenting a marked furrow at the origin of the beak, which is prolonged and thin; upper jaw somewhat larger than the lower; teeth numerous; length of the specimen taken six feet; dorsal in the middle; of a uniform ash-colour. This species was taken in the middle of the Indian Seas. In common with Mr F. Cuvier, we do not understand how M. Lesson should have ranked it with the *Delphinorhynci*. Baron Cuvier suspects it may be the same with the following species.

D. plumbeus, Dussumier, F. Cuv. General proportions of the genus; length eight feet; the dorsal starts from about a third of the anterior extremity; colour uniform leaden-grey, with the exception of the extremity and lower portion of the beak, which are whitish; teeth $\frac{36-36}{32-32}$, = 136. This species was detected off the Malabar coast by M. Dussumier, who states that they frequent the shores, and pursue the shoals of pilchards. Their motions are less rapid than those of their congeners, which are found in the midst of the ocean. The natives capture them in nets, but with much difficulty, because they seem to suspect their intentions, and very cautiously avoid the snare. The noise of a musket makes them flee in all directions; and after having sunk beneath, they take a direction different from that which their plunge indicated. These circumstances manifest something of that mental capacity with which the dolphin is generally supposed to be endowed.

D. frænatus, Duss., F. Cuv. Four and a half feet long; dorsal in the middle,—its length one-fifth of the whole body,—its form triangular and pointed; pectorals long and slender; colour black on the back, pale on the flanks, white on the belly, as is the lower half of the tail, the upper half being quite black; head black above, and of an ash tint on its sides, with a streak of a deeper hue, forming on the cheek a kind of bridle, extending from the commissure of the lips, under the eyes; teeth numerous, but their precise amount not ascertained. Taken by Dussumier to the south of the Cape-de-Verd Islands.

D. velox, Duss., Cuv.,[2] F. Cuv.;[3] *D. leger*, F. Cuv.;[4] *the swift dolphin*. Head and beak of the genus; beak long; length five feet; all the fins long and broad; dorsal over the middle; colour wholly black; teeth $\frac{41-41}{41-41}$, = 164. Dussumier met this species between Ceylon and the Equator. When one was harpooned the whole group instantly disappeared. They swam with extraordinary rapidity; hence their name.

D. longirostris, Duss., Cuv.[5] Our only information regarding this species is that in the Règne Animal taken from Dussumier's manuscripts. M. Dussumier captured it off the coast of Malabar. The number of its teeth exceeds that of most of the genus; the formulary is $\frac{60-60}{60-60}$, = 240.

D. superciliosus, Less. and Garnot, F. Cuv. Total length between four and five feet; dorsal somewhat beyond the middle; upper part of the body of a brilliant bluish-black colour, sides and under parts of a silvery whiteness; pectorals brown, on a white ground; but what especially characterizes this dolphin is a large white spot over the eye in front; another long white mark occurs on the sides of the body near the tail. Teeth, $\frac{30-30}{29-29}$; = 118. It was captured by Garnot off Van Diemen's Land.

D. Novæ Zelandiæ, Quoy and Gaimard, F. Cuv. Head and beak of the genus; lower jaw somewhat longer than the upper; dorsal large, triangular, rounded at top; pectorals of average size, falciform; tail small. Length between five and six feet. Colour dark brown above, lower part of beak and body dull white; a large yellow stripe commences at the eye, and terminates, growing narrower on the flanks, beneath the dorsal; tail of a slate colour, pale underneath; pectorals of the colour of white-lead, also the dorsal, both tipt all round with black; there is a black line over the snout, becoming larger towards the eye, which it surrounds; this line is accompanied on either side with a white line. Teeth, $\frac{43-43}{47-47}$; = 180.

D. cœruleo-albus, Meyen, F. Cuv. Facial line of the genus; snout more curved and compressed than in the common dolphin; pectorals more pointed; colour above, a deep steel-blue, as are the pectorals; a marking begins large at the dorsal, descends towards the commissure of the lips, and comes to a point half way between them; another commences at the pectorals and terminates in the black marking which surrounds the eye; this latter extends posteriorly, widening as far as the vent; the rest of the body is of a pure and brilliant white. M. Meyen observed this species on the east coast of South America. The specimen he examined was taken at the mouth of the Plata.[6]

D. Capensis, Gray.[7] The entire length of this animal is 81 inches; his widest girth 42. The back, lips, and fins are black; the belly white. Teeth about $\frac{50}{50}$, = 100. From the tip of the nose to the angle of the mouth he measures 13 inches; to the angle of the forehead 7; to the blower 7½; to the dorsal fin 38; to the pectoral 21. The length of the dorsal fin is 12; along the curve 12, and its perpendicular height 10; the length of the pectoral along the curve 13; the breadth of its base 5. The breadth of the tail is 18; and the length of each of its lobes along the curve 13 inches. This dolphin, says Mr Gray, is at once distinguished by the shortness of its beak. Its habitat is the Cape of Good Hope, whence it was sent to the Museum of the Royal College of Surgeons, London, by Captain Heaviside. Considerable discrepancy exists between the description and the plate by which it is accompanied.

D. dubius?, Cuv.,[8] Desm., No. 760. Less., F. Cuv. Cranium shaped like that of *D. delphis*, though somewhat smaller; beak more slender and pointed; upper jaw slightly conical, but not bent upwards; altogether smaller than the common dolphin. Teeth $\frac{37-37}{37-37}$; = 148. This species (still entitled to the name of *dubius*) was proposed by Cuvier from the examination of specimens, chiefly of crania, transmitted from the western coast of France.

D. niger?, Abel Rémusat., Lacép.,[1] Desm., No. 763. F. Cuv. Beak flat and very long; dorsal very small, and nearer the tail than the pectorals; colour mostly black, but white on the commissures of the lips, and margin of the pectorals, and part of the tail. Teeth more than 24 in each jaw. Introduced by Lacépède, on the faith of Chinese paintings procured in China by M. A. Rémusat. This species requires confirmation.

D. lunatus, Less., F. Cuv.; *Funenas* of the Chilians. Massive in its form; about three feet in length; beak slender; dorsal round at top; colour, a clear fawn shade above, gradually passing into white beneath; a brown and accurately defined cross is seen on the back on a line with the pectorals, and anterior to the dorsal. This small dolphin, according to Lesson, destroys an immense number of fish; and every morning at sunrise he noticed numerous troops of them, unceasingly diving in search of prey. By ten o'clock in the morning, when they had well breakfasted, they devoted themselves to play, and seemed delighted while striving which should rise the highest. He adds, that he saw this species only in the Bay of Talcahuana, in the province of Concepcion, where, however, it is extremely common.

D. minimus, Less., F. Cuv. About two feet in length; colour generally brown, with a white spot on the snout,—the latter slender. This species was seen by Lesson near the Moluccas, where they existed in thousands, frequently following each other in a uniform course forming two lines, in which they were arranged checquer-wise.

D. cruciger? Quoy and Gaimard, Less., F. Cuv. The flank is white, with a black line nearly throughout its whole extent; the dorsal is acute; total length but a few feet. This species was seen (but not taken) between New Holland and Cape Horn. It is suspected by M. F. Cuvier to be the same as the *Ph. bivittatus.*

D. albigena? Quoy and Gaimard, Less., F. Cuv. Colour generally black, with a white band on each side of the head, extending from the eyes as far back on the flanks as the dorsal-fin, which was of small dimensions. Observed (but not captured) by Quoy and Gaimard in the Antarctic Seas, and often seen by M. Lesson in the neighbourhood of New Holland.

D. Bayeri? Risso, Less., F. Cuv. Head equal to one-third the size of the whole body; snout much prolonged, obtusely pointed, and but little elevated, of the same form as in the dolphin. The opening of the mouth very large; teeth $\frac{34-34}{34-34}$, = 136; pectorals very broad; dorsal small and triangular; length forty-two feet; colour dull blue above, and whitish below. This species is doubtful and requires renewed examination. It was first noticed by Bayer, who considered it a cachalot;[2] but Risso having procured a drawing of what he believed to be the same animal, stranded at Nice in 1726, described it anew, and gave it Bayer's name. The characters stated above are from Risso's description. Baron Cuvier and his brother, with their eye fixed on Bayer's description, lean to the opinion that it was a cachalot.

D. Canadensis? Desm., No. 767, Duhamel,[3] Blain., F. Cuv.; *Dauphin blanc*, Desm. Head round, forehead elevated; beak pointed, and clearly distinguished from the forehead; length of specimen referred to twelve feet; colour white. Duhamel's description of this more than doubtful species is derived from information received from Canada. Whilst Desmarest regards it as a Delphinus, Baron Cuvier is disposed to refer it to the *Delphinorhyncus Geoffroyi*, and F. Cuvier to identify it with the Beluga.

D. Chinensis? Osbeck;[4] *D. Sinensis*, Desm. No. 759, F. Cuv. In the words of Osbeck, "it was like the common dolphin, but wholly of a white shining colour." He only *saw* this animal in the China seas. Bonnaterre[5] considered it a variety of *D. delphis*, Desmarest as a distinct species, and Baron Cuvier was disposed to regard it as a *Delphinapterus.*[6]

D. Bertoni? Desm. 768, Duhamel, Blain., F. Cuv. Forehead prominent; beak long and thick; upper jaw longer than lower; teeth confined to the latter; pectorals high in the body; the dorsal very small. Introduced by Desmarest on the imperfect data supplied by Duhamel. Habitat unknown; existence very doubtful.

D. Kingii? Gray.[7] "When the cranium is compared with the Beluga, the beak is found shorter by a half, and narrower in the exposed part of the maxilla, which edges the point of the blowers; the cavity of the cranium more globular, and the blower more anterior; teeth $\frac{9 \text{ or } 10}{9}\ \frac{9 \text{ or } 10}{9}$ small conical and recurved." Obtained on the coast of New Holland, and sent by Captain King to the British Museum.

D. longirostris?[8] Gray.[9] The existence of this our final species, is founded upon a cranium only, in Brooke's Museum. The beak, says Mr Gray, is more slender and depressed than that of the *D. Delphis*; the palate-bone is more strongly keeled; and the elevated central process of the upper surface of the beak is broad and convex. The length of the head is 6 inches; the beak $11\frac{1}{2}$; breadth of the latter, at the base, 3 inches. Teeth 48 to 50 in each jaw.

The PORPOISES, to which we now proceed, in their habits and dispositions very closely resemble the dolphins; and it is for the convenience of classification only that distinction is desirable.

GENUS (*e.*) PHOCÆNA, Cuv., Less., Gray. Head and snout short and gibbous, no beak, the facial line descending in a uniform connexity to the end of the snout; numerous teeth in both jaws; a dorsal fin. (See Plate XVI., figure 9.)

P. communis, Cuv., Less., &c.; *Delphinus phocæna*, Linn., Bon., Lacép., Desm., &c. The *Porpoise*, or *Porpess* of the English; also *Pellock* or *Sea pork*. The *Suinhual*, and *Springwhal*, and *Tumbler* of the Danes. *Maris Sus.*—the *Marsouin* of the French. (See Plate XVI., fig. 15.)[10] Head typical of that of the genus; lower jaw somewhat more projecting than the upper; dorsal nearly in the middle of the body, triangular; pectorals oblong; length from four to five feet; colour bluish-black above, fading on the sides to white underneath; pectorals dark brown; vertebræ, according to Lesson, 7, 14, 45, = 66; Tyson numbers them 60. Ribs, according to Lacepede, Tyson, Cuvier, and Lesson, 13, according to Hunter and Jacob,[11] 16; teeth $\frac{24-24}{24-24}$, = 96. Tyson.

The porpoise is found in all the seas of Europe, and in the Atlantic. In some parts of North America its skin, like that of the Beluga, is tanned and dressed with considerable care. It is shaved down from its natural thickness till it becomes transparent, and is then manufactured into articles of wearing apparel; it also affords excellent coverings for carriages. In a report of a committee of the House of Commons on the public works of Ireland, it is stated "that porpoises abound in almost innumerable shoals on the western shores of Ireland." It is desirable that they should be converted to the same economic purposes as in Canada.

[8] This name is most unfortunately chosen, and should certainly be changed by the learned author. It cannot be synonymous with the *D. longirostris* of Dussumier and the Règne Animal (see our p. 176) which is quite entitled to maintain its appellation.

[9] *Spic. Zool.* part i. p. 1.

[10] We are indebted for this original and very correct representation to the late Dr Macgillivray.

[11] *Dublin Phil. Jour.*, vol. i.

P. Grampus;[1] *Delphinus grampus*, Desm. 774, Hunter; *D. Orca*, Fab., Linn., Bon., Lacép., Shaw; also the *D. Gladiator* of Bon. and Lacep.; the *Grampus* of the English; *Epaulard* of the French; especially the *Buttskoff* of northern nations; the *Killer* and *Thrasher* of the Americans; the *Sword-fish* of the Greenlander; *Epée de Mer* of Bon., &c.; conjectured to be the *Aries marinus* of the ancients; Cuv. Oss. Fossil, t. v. p. 282. Head and snout of the genus; upper jaw somewhat larger than the lower; lower rather broader than upper; body elongated; from twenty to thirty feet in length; dorsal-fin central and very large, —four feet high; pectorals also very large, broad, and oval; colour black above, and white beneath, with a well marked line of junction; a white mark over the eye, and a black streak running forwards from the tail into the white portion; teeth $\frac{11-11}{11-11}$, = 44. Inhabits high northern latitudes, descending frequently into the Atlantic and German Ocean, and frequenting the coasts and friths.[2]

The grampus has the character of being exceedingly voracious and warlike. It devours vast quantities of fishes of all sizes, especially the larger ones. When pressed with hunger it is said to throw itself on every thing it meets with, not sparing the smaller Cetacea. Hunter found a portion of a porpoise in one which he examined. It is also said to make war on seals, and that when it espies them on the ice, it endeavours to drive them into the sea, where they become an easy prey. This species is often seen in small herds of six or eight, apparently amusing themselves, and chasing each other; and it is alleged, that when thus assembled they frequently attack the great Greenland whale. During this unprovoked and outrageous onset they are said to resemble so many furious mastiffs fighting with a wild bull: some seizing the tail and endeavouring to impede its murderous blows, whilst others attack the head, lay hold of the lips, or tear away the tongue. They have thus received the appellation of *Balænarum tyrannus* from the accurate Fabricius; and hence too the popular names of *Thrasher* and *Killer*.[3] We apprehend, however, that these bloody fights, recorded with such minute accuracy in many works on the Cetacea, stand in need of confirmation.

P. ventricosus? Hunter's "second species of grampus." Plate 18. *Delphinus ventricosus*, Bon., Lacép., Blain., Desm., F. Cuv. Head and snout of the genus; jaws projecting equally; dorsal fin of moderate size, situate somewhat behind the middle; pectorals long, not remarkably broad. Hunter's specimen was eighteen feet long; colour black above and whitish underneath, gradually merging into each other; no white or black markings. Cuvier and others have conjoined this with the preceding, and perhaps correctly; but, from the differences above indicated, we prefer for the present to follow the respectable authorities just named, and to keep it distinct. Hunter's specimen was caught in the Thames.

P. griseus, Less., F. Cuv.; *Delphinus griseus*, Cuv.[4] Desm., No. 775; *Paimpol porpoise* of Less.; *D'Orbigny's porpoise* of F. Cuv. Head and snout of the genus, though prominent; dorsal very elevated and pointed; pectorals enormously developed; total length ten feet; upper parts of the body and fins of a deep bluish-black, fading as it descends the sides, and giving place beneath to a dull white; no mark over the eye; vertebræ 7, 12, 42, = 61; ribs 12; teeth $\frac{0-0}{4-4}$, truncated; has been frequently stranded on the west coast of France.

P. compressicauda, Less. and Garnot, F. Cuv. Head round and prominent, terminating in a short obtuse point; upper jaw projecting slightly beyond the lower; length eight feet; dorsal somewhat behind the middle, triangular; pectorals small, attached low, form rather straight, and terminating in a point; tail rather small; leaden colour above, and whitish beneath; teeth $\frac{22-22}{23-23}$, = 90; lining of the mouth black. Captured by the crew of the Coquille, in latitude 4° S., longitude 26° W.

P. truncatus, *Delphinus truncatus*, Montague,[5] F. Cuv. Length twelve feet, circumference eight; black above, a purplish tinge gradually becoming dusky on the flanks, and sullied white beneath; lower jaw somewhat larger than the upper; teeth $\frac{20-20}{23-23}$, = 86, placed close together, circular, perfectly flat; some of the teeth nearly double the size of others, with no spaces between them; they were much truncated, some obliquely, and some at right angles. This species was taken in July, five miles up the Dart. Dr Fleming identifies it with the Tursio of Fabricius. We think his opinion is erroneous.

P. Capensis, Duss., Cuv.,[6] F. Cuv.[7] Head and snout of the genus, though somewhat flat; length four feet; dorsal somewhat beyond the centre, more than half a foot high; pectorals six inches long, three broad, rounded at their extremity; colour all over black, with exception of a white spot on each side, somewhat behind the dorsal; teeth, according to Baron Cuvier, $\frac{28-28}{28-28}$, = 112; according to F. Cuvier, $\frac{26-26}{23-23}$, = 98; cylindrical, pointed, and not compressed as in the common porpoise. M. F. Cuvier names it *D. cephalorhyncus*,—apparently an unnecessary innovation.

P. Homeii, Gray.[8] Colour above pure black; sides of the head and body clouded black and white; belly white; on each side an indistinct band commences immediately under the dorsal fin, and descends obliquely and backwards, till it terminates on the under and posterior part of the body; a dusky-coloured circle also surrounds the eye; below, the anterior part of the jaw, and a space of nearly a foot and a half before the tail, dusky; snout thick, pointed, and not readily distinguished from the anterior part of the head; teeth $\frac{40-40}{36-36}$, = 152, slightly curved with the convexity outwards; pectorals long and pointed; dorsal fin placed behind the centre, large, high, and pointed, its hinder edge falciform; tail semilunar; usual length six feet. Mr Gray states that this species is often caught in Table Bay. Is it distinct from the preceding?

P. (Grampus) Heavisidii, Gray;[9] *Delphinus hastatus*,

---

[1] Mr Gray has made this species the type of a new genus We do not, however, perceive the necessity or propriety of this.

[2] *Delphinus orca?*. Desmarest, besides the grampus above described, names a *D. Orca* (No. 765), noticed by Belon, and regarded by some as the *Orca* of the ancients. According to Cuvier, it has the facial line of a Delphinus. This opinion, however, rests upon a single sentence of Artedi, and its existence is very doubtful. It is said to inhabit the Mediterranean.

[3] The term *Thrasher* is also not unfrequently applied to a species of fox-shark (*Carcharias vulpes*), which, in common with the sword-fish, often attacks the whale.

[9] *Spic. Zool.* part i. plate ii.

Fr. Cuv.[1] Beak in a uniform line with the cranium, of moderate length, and large;[2] jaws equally projecting; "teeth 26 in upper and 25 in lower jaw;" dorsal fin not much elevated, placed somewhat beyond the middle; tail large; pectorals short. Length above five feet; colour generally black, head of a slate-colour, four markings underneath,—one in front of the pectorals, lozenge-shaped, two oval ones immediately behind them, and then a much larger one, covering a great part of the abdomen. The specimen which furnished Mr Gray with this description is in the Museum of the Royal College of Surgeons in London, and was sent thither by Captain Heaviside from the Cape, where M. Quoy again examined the species, in the cabinet of M. Verveaux, a naturalist settled in southern Africa. Their descriptions generally accord, though not in all particulars. Its habitat is presumed to be the neighbourhood of the Cape of Good Hope.

P. (*Grampus*) *obscurus*, Gray,[3] F. Cuv., Quoy.[4] Forehead and beak in a continuous line; teeth in the upper jaw 52, in lower 48, small and conical; dorsal fin two-fifths from the end of the snout. Length six feet. The back and upper part of the head black, the flanks and lower parts of the body white, with the exception of two bands running obliquely backwards,—one proceeding from the sides of the head, and terminating upon the pectorals, the other from under the dorsal, and terminating upon the belly. It is singular that these markings vary in different individuals, and are more apparent upon young than old animals. Mr Gray drew his description of this species also from a specimen in the Royal College of Surgeons, London. It had been sent from the Cape of Good Hope. M. Quoy, as in the former instance, found it in Mr Verveaux's museum.

P. Feres? Delphinus feres, Bon., Lacép., Desm., 766, F. Cuv. Head almost as high as long, much rounded on the summit, and suddenly sloping away anteriorly, where it terminates by a short round snout; jaws equal, covered with membranous lips; teeth $\frac{10-10}{10-10}$, $= 40$, some large, others small,—the former about an inch long, the projecting portion oval, round at the summit, and as it were divided into two lobes by a groove extending throughout their whole length,—the smaller teeth about half the size of the others. Length about fifteen feet; the whole body covered with a fine black skin.

This species rests solely on the authority of Bonnaterre, who received from the Abbe Turles of Frejus, a drawing of the skeleton, and a description of the external aspect. A shoal of about 100 were captured, after a hard struggle by the Provençals.

P. bivittatus? Lesson, F. Cuv. Snout short and conical; dorsal moderately high, black, and placed over the middle of the animal; pectorals thin, white, with the anterior edge black; tail brown, sloped in the middle; two feet and a half long; slender in its form; upper part of the body of a deep shining black; belly and lower jaw white; there is a large slash of satiny white running along each side of the body, but interrupted in the middle, opposite the dorsal, where the two portions of the band thus separated are enlarged. Suspected by F. Cuvier to be the same as *D. cruciger*. Seen by Lesson in great numbers off Cape Horn.

P. Agluk? Pallas, Chamisso, Less. Length thirteen feet; dorsal large; teeth small and numerous; colour black, with a white lateral streak passing from the commissure of the lips to below the pectorals, and another commencing before the dorsal, and proceeding obliquely underneath towards the origin of the tail.

P. intermedius? F. Cuv.; *Delphinus intermedius*, Gray.[5] This species is proposed by Mr Gray from an examination of a cranium in the British Museum, of the origin of which he knows nothing. He remarks that the cranium is very like that of *P. griseus*. The teeth, however, are $\frac{11-11}{10-10}$, $= 42$, whilst the last named species has seldom more than two or three in the lower jaw. This approximates the former to the *Orca* of Fabricius, from which, however, it differs in the small size of the temporal fossa, in the width of the temporal ridge, and the greater size of the space for the attachment of the occipital muscles.

GENUS (*f.*) GLOBICEPHALUS, Less. Characterized by having no visible snout; the head being nearly globular, and the mouth towards the under portion. (See Plate XVI., fig. 10.)

G. Deductor, Less.; *Delphinus globiceps*, Cuv.,[6] Desm. No. 777; *D. Melas*, Traill; *D. Deductor*, Scoresby; *Ca'ing whale* of Orkney; *Uyea whale*, Neill; *Grind whale* of Feroe; *Butshead* of the Danes. (See Plate XVI., fig. 16.) Head obtuse, upper part very much rounded; body thick; dorsal small; pectorals very long and narrow; colour generally black, with a white mark under the throat, extending along the belly; length about twenty-two feet; teeth $\frac{14-14}{14-14}$, $= 56$, conical, sharp, somewhat curved at their summit, and very apt to disappear; vertebræ 7, 11, 37, in all 55; ribs 11. Inhabits the northern shore of Europe, Iceland, Feroe, Shetland, Orkney, and the British and French coasts. Egede is perhaps the first author who makes mention of the *Deductor* under the name of *Butshead*; and he was soon followed by Duhamel, who gave a figure of one taken at Havre, under the name of "the porpoise with the round snout." In 1806 Dr Neill gave a more extended and interesting account of the species, under the name of *Uyea Sound* or *Ca'ing whale*, than any which had previously appeared;[7] and three years after Dr Traill published its first accurate description, under the name of *Delphinus melas*,[8] with a drawing, afterwards republished with additional details in Scoresby's work.[9] In 1812 an interesting memoir concerning the same animal appeared from the pen of Cuvier. He bestowed upon it the name of *Delphinus globiceps*.[10]

Of all the Cetacea this would appear to be the most sociable, often herding together in innumerable flocks. We may supply a few facts which establish this point. From an old history of the Feroe Islands, quoted by Mr Scoresby, it would appear that the inhabitants had long been in the habit of hunting and capturing them in great numbers. In the year 1664, on two excursions only, they killed about 1000; in the year 1748, 40 individuals of this species were seen in Tor Bay, and one seventeen feet long was captured; in 1799, about 200 ran ashore in Fetler, one of the Shetland Isles; and, in 1805, as mentioned by Dr Neill, in February 190, and in March 120 more, out of a herd of about 500, were forced ashore in Uyea Sound, in Unst; in 1806, 92 were stranded in Scalpa Bay, Orkney; in 1809 and 1810, 1100 of these animals approached the shore of Hvalfiord, Iceland, and were captured; in 1812, 70 were chased ashore near the village of Bloubalzbance, on the coast of Bretagne; and, in 1814, 150 were driven into Balta Sound, Shetland, and were there despatched. These are only a few of the instances in which, in modern times, an extensive capture of the *Deductor* has taken place; and we may add, that it is alleged to have been seen both off the American coast, and in high latitudes in the Pacific.

---

[1] The multiplication of specific names is much to be lamented. We have here one of English origin, given by Mr Gray, and another from a French source, supplied apparently by M. F. Cuvier, but possibly by M. Quoy. The priority of publication ought to regulate our choice, and on this principle we have given due weight to the name of *Heavisidii*.

[2] We confess we have much difficulty in satisfactorily classifying these species so slightly sketched by Mr Gray: the descriptions would almost ally them with the Delphinorhynci.

[10] *Ann. du Mus.* t. ix.

It would be interesting to ascertain from what mental peculiarity it results that this animal is so frequently stranded, so easily hunted, and so readily made a prey. We have seen enough to demonstrate that they are most sociable in their habits; and we may now remark that they seem moreover to be endowed by an instinct very useful, doubtless, on the whole, whereby they are almost irresistibly induced to follow the guidance of the oldest and most experienced of their number. In the words of Dr Traill, they seem generally to follow one as a leader with blind confidence; and Dr Neill remarks, that the main body of the drove follows the leading whales as a flock of sheep follows the wedders. Hence the natives of Shetland well know that if they are able to guide the leaders, they are sure likewise of entangling multitudes of their followers. This trait is strikingly illustrated by a circumstance of which Dr Traill was a witness. "I once," says he, "was in a boat when an attempt was made to drive a shoal of them ashore; but when they had approached very near the land, the foremost turned round with a sudden leap, and the whole rushed past the boat." It is from this peculiarity in their mental constitution, that Dr Traill, it would appear, applied to them the appellation of *deductor*.

G. Rissoanus, Less. *Delphinus Rissoanus*, Cuv. Head large and round, upper jaw longer than the lower, dorsal high, in form of a scaline triangle, situated near the middle; pectorals large, broad and thick. Length nine or ten feet. Colour of the males a bluish-white, of the females a uniform brown, and both marked with irregular white lines, and brown spots. It inhabits the Mediterranean. (See Plate XVI., figure 8.)

G. leucocephalus? Less., Fr. Cuv. Head short, conical and truncated; dorsal very narrow, and acute at the summit. Length about six feet; body of a deep grey colour; head and neck of a dazzling whiteness. Lesson *saw* this species in the Archipelago of Pomotous, but did not capture any of the shoal.[1] He likewise mentions another observed in similar circumstances. It may be called the

G. fuscus? Less. Head completely truncated; dorsal high, falciform. Length ten or twelve feet. Colour a uniform brownish-black. The French naturalist was informed by the captain of an English whaler, that this was the *black fish* of the whalers, which, though very active, they were anxious to catch, because they found in its head a matter analogous to spermaceti.

We now proceed to a genus as yet but slightly known, though interesting and peculiar. It consists of those Cetacea which have two dorsal fins. This character, more curious than important, does probably not produce any marked difference between the habits of this little group and those of its congeners. It was established by M. Rafinesque Smaltz, and contains at present only two species.

B. Those which have two dorsal fins.

GENUS (*g.*) OXYPTERUS, Rafinesque Smaltz, Less., F. Cuv. Two dorsal fins.

O. Mongitori, Rafinesque Smaltz, F. Cuv. Named but not described by Smaltz in his *Precis de Sémiologie*, p. 13. He observed the animal in the Sicilian seas.

O. Rhinoceros; Delphinus Rhinoceros, Quoy and Gaimard, Less., F. Cuv. (See Plate XVI., figure 18.) A fin on the head inclined backwards, like that on the back; length ten or twelve feet; upper part of the body as far as the dorsal fin spotted with black and white.

"In 1819," say these interesting writers (Quoy and Gaimard), "in going from the Sandwich Islands to New South Wales, many dolphins, in troops, performed rapid evolutions about our vessel. Every one on board was surprised to perceive that they had a fin upon their head, bent backwards, the same as that on their backs. The size of this animal was about double the size of the common porpoise; and the upper part of its body to the dorsal fin was spotted black and white. We did our best to examine them all the time they accompanied us; but although they often passed the prow of the vessel, with the highest part of the back out of water, yet their head was so submerged, that neither M. Arago nor we could discover whether their snout was long or short; and their habits did not assist us on this point, because they never sprang above the wave, as is common with other species. From this very singular structure we have given them the name of *Rhinoceros*."[2] Though, from the circumstances detailed, our authors could not supply an accurate drawing, yet Messrs Quoy and Gaimard have furnished a sketch of the appearance of the species, which we copy from their atlas.

C. Those which have no dorsal fin.

GENUS (*h.*) BELUGA, Less. Gray. The osteology of the cranium, according to Baron Cuvier, supplies generic characters which distinguish this from the neighbouring genera. The form of the head is obtuse, conical, and rounded. The genus is moreover distinguished from the *Globicephalus* by having no dorsal fin; and from the *Delphinapterus* by having no prolonged snout-like flattened beak.

Beluga arctica, Less. *Delphinapterus beluga*, Lacép. *Beluga*, Shaw. *D. Leucas*, Linn. *D. albicans*, Fab. Bon. *White whale* of English whalers. (See Plate XVI., figure 17. Head obtuse and rounded; mouth small; teeth short and blunt $\frac{9-9}{9-9}$; no dorsal fin; pectorals large, thick, and oval; tail large and powerful. Total length from twelve to eighteen feet. Colour, of a light cream-colour. The shape of this animal is highly symmetrical, and at once suggests the idea of perfect adaptation to rapid progressive motion in water. Its head is small and somewhat lengthened, and over the forehead there is a thick cushion of fat; the body continues to swell as far as the pectoral fins, and from this point gradually diminishes to the setting on of the tail. The tail is powerful, bent under the body in swimming, and worked with such force that it impels the beluga forward, says Giesecké, with the velocity of an arrow. The colour is usually a uniform and beautiful cream-colour, whilst the younger ones are marked with brownish spots, and are somewhat of a blue or slaty colour. Dr Scoresby remarks, that he has seen some of a yellowish hue, approaching to orange; and this agrees with the statement of Fabricius, who says they are white, sometimes tinged with red. Many contradictory accounts are given of the number of teeth, in consequence, no doubt, of the fact, that in the beluga, as in most of the other whales, these parts have the greatest tendency to drop out as the animal becomes aged. Anderson states that it has no teeth in the upper jaw, and that this is the universal opinion of the Greenland fishers, while there are eight on each side in the lower;—thus, $\frac{0-0}{8-8}$. Dr Neill gives $\frac{9-9}{6-6}$, and Crantz $\frac{8-9}{6-6}$. Cuvier, however, states them as $\frac{9-9}{9-9}$, = 36; so agreeing with Fabricius. But if we are so slow in arriving at certainty respecting the dental apparatus of the beluga, when are we, by this means, to determine species in any of the other Cetacea?

---

[1] *Voyage de la Coquille*, t. i. p. 184.

[2] *Voyage de M. Freycinet.* Zoologie, p. 86.

Sir Charles Giesecké describes the white whale as a migratory animal, which visits Greenland every year regularly about the end of November. He remarks that, next to the seal, it is the most useful animal captured by the natives, as it comes at a season when their provisions are extremely scanty. It arrives in herds, in stormy weather. It is taken by harpoons and strong nets; in the latter case the nets are extended across the narrow sounds between the islands, and when a shoal is thus interrupted in its course seaward, the individuals are attacked with lances, and great numbers are frequently killed. The flesh is somewhat similar to that of beef, of a bright red colour, though somewhat oily. According to Hans Egede, "when it is marinated with vinegar and salt, it is as well tasted as any pork whatever; the fins also, and the tail, pickled or sauced, are very good eating, so that he is very good cheer. The oil is of the whitest, best, and finest quality."[1] Some of the internal membranes are used for windows, and some as bed-curtains; the sinews furnish the best sort of strong thread.

GENUS (*i.*) DELPHINAPTERUS, Cuv. Less. Distinguished from the dolphins by having no dorsal-fin, and from the beluga by having a slender beak, flattened transversely, and separated from the head by a marked furrow.

D. Peronii, Cuv. Less. *Delphinus Peronii*, Lacép. Desm., No. 771, D. *Leuco-grampus*, Peron. *D. Chilii* of Kotzebue. (See Plate XVI., figure 19.) Snout obtuse, depressed at the extremities and edge, thus forming a short beak; pectorals and tail large; colour above of a deep bluish-black, beneath brilliant white, except the edge of the pectorals, which is black. Length between five and six feet. Teeth $\frac{39-39}{39-39} = 156$, all slender and very pointed. High southern latitudes are the resort of this species. The historian of the voyage of Baudin met with them to the south of Van Diemen's Land; Dr Quoy saw them near New Guinea, as did M. Lesson, off Magellan's Straits and the Falkland Islands. Many of them, according to the last named author, surrounded the corvette in January 1823, on the vessel entering the Southern Ocean, and one was harpooned by the sailors, which enabled him to give a more accurate account than any previously supplied. It is elegant in its form, regular in its proportions, sleek, and especially remarkable from appearing to be covered with a black cloak. Its snout, as far as the eye, is of a silky and silvery whiteness, so are the sides and pectorals, the abdomen, and part of the tail. A large scapulary of a deep bluish-black colour, rising at the eyes, where the white appears like a cross, is pointed and bent on the flanks so as to cover the upper part of the back only. The iris is of an emerald-green.

D. Commersonii, Cuv. Less. *Delphinus Commersonii*, Lacèp. Desm. 772. *The Jacobite* of the French. Snout flat and slender; body generally silvery-white; the snout, tail, and pectorals tipt with black; about the size of the common porpoise. Commerson, who regards this as one of the most beautiful inhabitants of the ocean, encountered it in the Straits of Magellan. Lesson met with it at the Falkland Islands.

D. Senedetta? Lacèp. This species is rejected by Cuvier.[2]

D. Epiodon? Rafinesque Smaltz, Desm., 786, **F. Cuv.** Body elongated, attenuated posteriorly; snout rounded; lower jaw shorter than the upper; many obtuse teeth, which are all alike in the upper jaw; none in the lower. No dorsal-fin. This animal was taken in the Sicilian Seas in 1790, and Rafinesque seems to have described it from a drawing. We have no further information respecting it.

It may here be remarked, that we have now discussed to the extent our limits will allow our first subdivision, consisting of Cete with ordinarily proportioned heads, and numerous teeth; it includes nine genera, and about fifty species. The direction of the facial line has chiefly, though not solely, regulated us in this avowedly artificial, and, it should not be forgotten, not very important arrangement of genera. We shall here supply a tabular view of the classification of the whole of the preceding subdivision:—

A includes those which have a dorsal fin.

Genus *a.*	Beak long, cylindrical, with molar-like teeth, . . .	*Inia.*
b.	Facial line of nearly uniform slope, beak peculiarly long,	*Soosoo.*
c.	Facial line of nearly uniform slope, beak or snout short,	*Delphinorhyncus.*
d.	Facial line marked by a sudden fall, beak short, .	*Delphinus.*
e.	Facial line of uniform slope, no beak, snout short, .	*Phocœna.*
f.	Head globe-shaped. No beak, no snout, . . .	*Globicephalus.*

B Those which have two dorsal fins.

g.	. . . . .	*Oxypterus.*

C Those which have no dorsal fin.

h.	Head globe-shape (from only a single species, called) .	*Beluga.*
i.	Having a beak, from απτερος "without a fin." . .	*Delphinapterus.*

SUBDIVISION II.—HETERODONTES. Head of ordinary proportion. Teeth few, and of various forms,—sometimes wanting. Blow-hole single.

Ever since Cetology has been studied as a science, the teeth, as in the other orders of Mammalia, have received the most marked attention. The two great orders into which Lacèpéde divides the *ordinary* Cete (which alone he considers), are founded on the fact, that some possess teeth, while others want them; and three of his ten genera repose solely on the peculiarities of the dentition. Since his time increased attention has been paid to these important parts. Blainville introduced the term HETERODON,—in which subdivision he includes those genera of which the teeth, in number, form, and situation, are various and in some respects anomalous. Sometimes, as in the Narwhal, they are scarcely in the mouth at all; and several genera are believed to be still more destitute of teeth. Desmarest and Lesson have followed in Blainville's track, and pursuing the same course we shall now discuss, under the name of HETERODONTES, a perplexing and somewhat anomalous group. It includes the *Narwhal*, the *Diodon*, the *Hyperoodon*, the *Aodon*, and the *Ziphias*,—which last comprehends some of the most important fossils which have been discovered.

GENUS NARWHALUS, Lacép., Cuv., Desm. *Monodon*, Lin., Bon. *Sea Unicorn* of whalers. This genus has no teeth properly so called, but only two long tusks straight and pointed, implanted into the outer maxillary bones, and projecting forwards in the axis of the body. It has no dorsal fin.

This long established genus was formerly made to include several species. Bonnaterre had two, and Lacèpéde and Desmarest three; the first and last of these, viz.—*N. vulgaris?* Lacép., Desm. No. 707, *Monodon monoceros*, Fab., Linn., *Narwhal*, Bon.; and the *N. Andersonii?* Lacèp., Desm. No. 789, are now rejected as having been introduced on insufficient grounds. There remains, therefore, only one species, viz.

---

[1] *Description of Greenland.*

[2] *Règne Animal*, 291.

N. microcephalus, Lacép., Desm. No. 788, Dr Fleming. *Monodon monoceros*, Linn., Cuv., &c. *Sea Unicorn.* (See Plate XVII., figure 2.) This singular creature has rarely two tusks developed at the same time; the single tusk or horn (as it is called) has usually spiral markings, though these are sometimes absent; its length is from seven to ten feet; and that of the whole animal twice or thrice as much. The head is round and suddenly truncated; body slender; no dorsal fin; pectorals short; eye small; colour generally light-grey, variegated with darker spots. Vertebræ 7, 12, 35, = 54 (Scoresby); ribs twelve pair. The length of the narwhal is usually stated to be about fifteen or sixteen feet, which is to be understood exclusive of the tusk; so that, with this striking appendage, it reaches to from twenty to twenty-seven feet. Besides the elongated tusk, like a spirally twisted spear, there is literally no other teeth. When very young, the germ of a tooth can be discovered on each side of the mesial line, the subsequent elongation of one of which produces the sharp weapon of the adult. Sometimes both germs are developed, and produce two horizontal and diverging spears. Among a considerable number of instances which might be adduced, we mention only one of this more perfect development, which is preserved in the Museum of Roeding at Hamburgh. In this specimen, when they start from the bone (see Plate XVII., figure 1), the tusks are only two inches apart; but they steadily diverge till their points are thirteen inches asunder. The left tusk is seven feet five inches and the right seven feet long. It much more frequently happens, however, that only one of the germs grows, while the other becomes almost obliterated, or remains shut up in the bone, like an inert osseous nut. It is curious that the tusk is usually found on the left side,—a fact for which we believe that no sufficient reason has yet been assigned. At one time it was stated that the tusks were peculiar to the males; this, however, is now found to be incorrect, and it seems doubtful whether they are not as common in the one sex as the other. Fabricius' account is probably the correct one, "*Cæterum, tam feminæ, quam mares dentatæ.*" Two uses of the horn may be inferred from the statements of Dr Scoresby:[1] one, that it is occasionally employed in breaking the thinner ice, whereby the narwhal can more easily carry on respiration than it otherwise could; and the other, that, by the horn, it attacks its prey, first killing the great fish on which it is to feed, because, from the smallness of the mouth, it could not possibly devour them until it had put an end to all resistance.

The sea-unicorn is regarded by the Greenlanders as a migrating animal. Its favourite resorts seem to be among the ice-islands of the pole, and the creeks and bays of Greenland, Davis' Straits, and Iceland. The natives regard it as the precursor of the great *Mysticetus*, and, as soon as it is noticed, they prepare in earnest for the fishing of that vast monster. Narwhals are quick, active, usually inoffensive animals, which swim with considerable velocity. When harpooned they dive in the same manner, and almost with as much rapidity, as the true whale, but not to the same depth. They generally descend about 200 fathoms, then return to the surface, and are despatched with the lance in a few minutes. The blubber supplies about half a ton of oil, which is regarded of first-rate quality. The Greenlanders consider both the oil and flesh as very delicious nourishment. At a time when the origin of the horns of these animals was less known, and when they were more rare than now, they were considered as invaluable. The physician, and still more the charlatan, employed them, and superstition converted them to its use; for it is stated that the monks in various convents procured the *true* horn of *the* unicorn, which was believed to be endowed with unheard-of powers, and obtained for them far and near the credit of curing the most inveterate diseases. The ivory is esteemed superior to that of the elephant; in the words of Giesecke, it far surpasses it in all its qualities. It is said that the kings of Denmark possess a magnificent throne made of these precious horns, which is preserved with great care in the castle of Rosenberg. They still form a highly valued article of trade.

ANARNACUS, ? Lacép. We shall here notice the *Anarnak*, the fourth genus of Lacépède, the fifth of Lesson, the nineteenth species of Fabricius,—a kind of Monodon according to Bonnaterre, and of Heterodon according to Desmarest. The characters are, two small teeth at the extremity of the upper jaw, and no traces of any other teeth in either jaw.

Anarnacus Groenlandicus? Lacép. Less. *Monodon spurius*, Fab. Bon. *Delphinus Anarnak*, Desm. No. 780. The two teeth are scarcely an inch in length, obtusely conical, slender, and curved at their summit; body elongated; whole size inconsiderable; a dorsal-fin; colour black; the flesh said to possess a laxative property. This genus rests solely upon the authority of Fabricius. He says it frequents the high northern seas, and seldom approaches the coast.

GENUS DIODON, Lesson. The lower jaw supplied with two teeth only, the upper having none; the lower jaw the longer and stronger, somewhat convex; forehead depressed.

D. Sowerbyi, Less. *Delphinus Sowerbyi*, Blain., Desm., No. 785, Fr. Cuv. *Physcter bidens*, Sowerby. (See Plate XVII., figure 5.) Lower jaw longer than the upper and stronger, with two short *lateral* teeth; upper jaw sharp, let into the lower, having two impressions corresponding to the teeth; eye small; spiracle lunated, horns pointed forward; colour black above, nearly white beneath, marked with streaks. Sowerby's specimen was sixteen feet long and eleven in circumference at the thickest part. Dorsal fin over the vent. This animal was cast ashore near Brodie-House, Elginshire.[2] Its ordinary habitat and habits are wholly unknown.

D. Desmaresti, Risso. Less. Fr. Cuv. Upper jaw short and without teeth, lower much longer, convex, and having near its extremity two large conical teeth, three inches long, one broad; eye small; pectorals short; dorsal fin over the vent; tail large and festooned; upper portion of the body of the colour of polished steel, with a number of white streaks arranged without regularity; belly white; inside of the mouth bluish-black. Risso's specimen was fifteen feet long. According to the naturalist of Nice, who alone has described and drawn this animal,[3] it affects the deep waters of the Mediterranean, and comes towards the coast in the months of May and September. It very much resembles the preceding.

GENUS HYPEROODON, Lacép. Cuv. Less. Fr. Cuv. Three great bony maxillary and occipital crests, separated by deep furrows, which rise over the cranium and occasion a remarkably rounded and prominent forehead; beak short and very strong; *palate supplied with a number of small false and tuberculated teeth?* blow-hole crescent-shaped, horns pointing forward.

H. Honfloriensis, Less. *Delphinus Hyperoodon*, Desm. No. 784. *H. Butskof*, Bon. Lacép.; including also *D. bidentatus*, Bonnat. *D. Diodons*, Lacép. *D. Hunterii*,

---

[1] See some interesting remarks in a *Journal of a Voyage to the Northern Whale-Fishery*, 1823.

[2] Sowerby's *Brit. Miscel.* 1806. We beg to observe that the generic title of DIODON is extremely ill-chosen,—seeing that it has been long ago applied by all naturalists to a genus of plectnognathous fishes.

[3] *Hist. Naturelle de l'Europe Mérid.* Nice. 1826. T. iii. pl. 3.

Desm. 782: called *Bottle-nosed whale* by Hunter, plate 10. *Bottle-headed whale* of Dale. (See Plate XVII., fig. 8). False teeth in the upper jaw, and, allowing these have no existence, still the name has been affixed by Cuvier to a genus which undoubtedly exists, and which possesses marked peculiarities in the prominence of the forehead, and the shortness and flatness of the beak, produced by the maxillary crest. The head is higher than it is broad; the pectorals are very small; the dorsal fin, but little developed, is within a fifth of the length from the tail. Colour brownish-black above, verging towards white beneath. Usual dimensions from sixteen to forty feet. Vertebræ 7, 9, 26, in all 42 (Jacob); ribs 9 pair. Two strong teeth at the extremity of the lower jaw.

This genus was admitted upon the authority of M. Baussard, an officer of marine, who examined two individuals, mother and cub, which were stranded near Honfleur, and who, with laudable zeal, published an account of them in the year 1789.[1] The circumstance on which rested the claim of these specimens to be considered generic was the total want of teeth in either jaw, and their having the upper jaw and palate furnished with small unequal and hard points, which were about half an inch long in the cub, and somewhat larger in the mother. Baussard's memoir appeared two years later than Mr Hunter's description of his *B. bidentatus*,[2] which was admitted as distinct by Bonnaterre, Lacépède, &c. Hunter says nothing of false teeth in the palate, and mentions that two strong and robust teeth existed at the extremity of the lower jaw. These, then, were long regarded as two species. Bonnaterre, in describing Baussard's specimens, very unaccountably assigned to them two teeth in the lower jaw,[3] and thus very naturally misled Lacépède, Illiger, and for a time even Baron Cuvier.[4] It was probably when holding this opinion, that Cuvier, in visiting Mr Hunter's museum, and examining the head of his *Bidentatus*, came to the conclusion that Baussard's and Hunter's specimens were one and the same species, belonging, however, to a genus distinct from all others. He attached the title of *Hyperoodon* to both.

H. Chemnitzianus? D. Chemnitzianus, Desm., Blainv. Length twenty-five feet; two teeth at the extremity of the moveable or lower (but Desmarest has it upper) jaw; upper jaw, much less thick and strong; body wholly black. A considerable quantity of spermaceti was taken from the head of this species which was captured near Spitzbergen in 1777. It is the *Balæna rostrata?* of Chemnitz, which Blainville and Desmarest have classed among the Heterodons, and which Cuvier suggests would be better united with the present genus. But in truth the description is so short that nothing satisfactory can be made of it.[5]

Genus Aodon, Lesson. No teeth; no tubercles on the palate; no whalebone; body fusiform; forehead prominent; jaw in a continuous line with the forehead.

A. Dalei, Less.; *Delphinus Dalei*, Blain., F. Cuv.;[6] *D. edentulus*, Schreber, Desm. 783; *Delphinorhyncus micropterus*, Cuv.[7] (See Plate XVII., figure 6.) Body fusiform; some appearance of a neck; forehead prominent; spiracle curved forwards; jaws prolonged in form of a subcylindrical beak, and in the same plane with the facial line, the upper somewhat shorter than the lower; no teeth, or only rudimentary; no rugosities on the palate; pectorals and dorsal very small; tail broad; colour shining-grey, dark above, light beneath; vertebræ seven, nine, and from fifteen to twenty more; ribs nine; maxillary and intermaxillary bones rising high above the frontal. This beautiful animal stranded itself near Havre; its resorts, habits, &c. are wholly unknown. The species was originally founded on the *Bottlehead* of Dale, and designated as *D. edentulus* by Schreber, Blainville, and Desmarest. The name was applied afresh to a specimen stranded near Havre in 1825, and examined by Drs Surirray and Blainville. If Hunter was right in saying that his *Bidentatus* was the same as Dale's, then the authors last quoted were incorrect in associating that name with the Havre specimen. This was Cuvier's opinion, who says (in *Règ. An.*) that the name was "*très impropre.*" Nevertheless we retain it, as we believe the species has been accurately described under that designation.

The Genus Ziphias being fossil, we omit. Cuvier states that their craniums ally them to the Cachalots, and still more to the Hyperoodons. He has distinguished three species, all of which appear to be destitute of teeth.

Subdivision III. Great-headed Whales.

We now advance to the last subdivision of the ordinary whales, which is distinguished from the others by having the head much larger than the usual proportions, amounting to one-fourth, or even to one-third of the whole bulk. Though this section includes by far the most important animals of the order, yet the number it contains is small, extending to but three genera, and about twice as many ascertained species. All of these, from their extraordinary magnitude, and the majority from their extreme value, have from time immemorial engaged the liveliest and most general interest; and hence, notwithstanding their gigantic size, their structure is better known, and their habits and disposition better ascertained, than those of most others of the race.

Genus Cachalot,[8] Bon. Desm. Cuv. *Physeter*, Linn. Head nearly one-third of the whole size; blow-hole single; no baleen; no teeth, or only rudimentary, in the upper jaw; lower jaw narrow, elongated, received into a furrow in the upper one, armed on each side with a range of strong teeth. Produces the *spermaceti* and *ambergris* of commerce.

C. macrocephalus, Cuv. Bon. Lacép. *Physeter catodon*, Linn. *The Spermaceti Whale.* (See Plate XVII., fig. 11.) One or more humps on the back; lower jaw having from 20 to 23 teeth on each side, a few rudimentary ones hid under the gums in the upper jaw; length 80 feet; colour greenish-black above, whitish beneath. Vertebræ, 7, 14, 38, = 59.

Some of our readers may perhaps be surprised, that under the generic term Cachalot we introduce to their notice only a single species. This we do, not because we deny the existence of others, but because these have not hitherto been accurately described or established. Desmarest some years ago admitted three sub genera and eight species; and Lacépède has three genera and eight species, including his cachalots, physalus, and physeter.[9] Every one who, previous to our own days, had attempted to reconcile the many contradictory accounts which have been given of this extraordinary animal, seems in his turn to have been foiled; and it was reserved for Cuvier to cut at all events, if not to unravel, the entangled knot. He remarks: " The history of this animal is so perplexed, so many beings have been confounded with it, and the species have been so wantonly multiplied, that to obtain more precision on the subject, I have been obliged to review, chronologically, every thing that naturalists have written concerning it." And after making this review, he concludes, " Will it now be regarded as great temerity in me, after having produced the ideas of so many learned men, to maintain that up to the present time, there is no ground to suppose that there is more than a single species of Cachalot?"

[8] From *Cachou*, a tooth, in the Basque tongue.

[9] We shall here exhibit the older classification by copying that of Lacépède.

I. Genus *Cachalot.* Having blow-hole at the extremity of the snout.
  1. Subgenus. Those which have a bump or bumps on their back. 1st sp. *C. macrocephalus.* 2d, *C. Trumpo.* 3d, *C. Swinwhal.*
  2. Subgenus. 4th sp. *C. albus.*
II. Genus *Physalus.* Having blow-hole on the head, not at the extremity of the snout. 5th sp. *P. cylindricus.* Having a bump on the back.
III. Genus *Physeterus.* A fin on the back. 6th sp. *P. Microps.* 7th, *P. Orthodon.* 8th, *P. Mular.*

We take our description very much from that supplied by Cuvier.[1] It is one of the largest Cetacea, attaining the length of 70 and 80 feet; its head is very large in all its dimensions, and the length of that part does not appear to have been much exaggerated when stated to be about a third of the whole body; the snout is very obtuse, and apparently truncated; the lower jaw, very narrow, is received between the upper lips as in a furrow, the teeth entering, when the mouth is shut, into cavities on the edge of the palate. The blow-hole, 12 inches long, in the form of an *ſ*, is on the anterior extremity of the head, in the centre of a round protuberance, formed of thick fibres, which act as a sphincter. The pectorals are small and obtuse; there is a small dorsal protuberance only, far down the back, and sometimes two or three smaller ones; the tail is very large. The colour above is a blackish and somewhat greenish-grey; below it is whitish, as also round the eyes. The immense cavity at the upper part of the head, covered only by a tendinous but very resisting integument, is divided interiorly into compartments, also tendinous, which communicate with one another, and into great cells filled with oil, which is fluid when the animal is alive, but after death assumes the concrete form with which we are familiar under the name of spermaceti. This substance was long absurdly regarded as the brain, which, in truth, occupies a very small space in the interior of the cranium. The ambergris again, is found in the intestinal canal, but in what precise part, and under what exact circumstances, has not yet been ascertained.[2]

From the popular and highly interesting statement of Mr Beale,[3] we learn that the blubber on the breast of a large whale is about 14 inches thick, and on most other parts of the body from 8 to 11. This covering the southern whalers call the *blanket;* it is of a yellow colour, and when melted down yields the sperm oil. He states, that the opening of the ear is of sufficient size to admit a small quill. The throat is capacious enough to give passage to the body of a man, in this respect presenting a strong contrast to the contracted gullet of the Greenland whale. According to Mr Beale, the peculiarity of the sperm-whale which strikes every beholder, is the unwieldy bulk of the head; but this, instead of being an impediment, is conducive to its agility, for the greatest part of it containing oil, the head receives a tendency to rise so far above the surface, as to elevate the blow-hole for the purposes of respiration; and should the animal wish to increase its speed to the utmost, the narrow lower portion of the head, which bears some resemblance to the cut-water of a ship, is the only part exposed to the resistance of the water, and it is thus enabled to press its ponderous way, with the greatest ease, along the ocean. " LORD, how manifold are thy works! in wisdom thou hast made them all." " They that go down to the sea in ships, that do business in the great waters; these see the works of the LORD, and his wonders in the deep."

Mr Beale's observations on the swimming of this whale are curious. He states that, when undisturbed, it passes tranquilly along, just below the surface of the water, at the rate of about three or four miles an hour, its progress being effected by a gentle oblique motion of the tail from side to side. When proceeding at this rate, the body lies horizontally; the water, somewhat disturbed by its progress, is known by the whalers under the name of " white-water," and from its appearance, an experienced eye can, from a distance of several miles, judge of the rate at which the whale is advancing. In this mode of swimming, it is able to attain a velocity of about seven miles an hour. When it swims at a more rapid rate, the action of the tail is altered, the water is struck directly upwards and downwards, and each time the blow is made with the lower surface, the head sinks down eight or ten feet; and when the blow is reversed, it rises out of the water, presenting to it only the sharp cut-water portion. This mode of swimming is what is called *going-head-out*, and in this way the whale can attain a speed of 10 or 12 miles an hour, which is probably its greatest velocity.

The sperm-whale is remarkably distinguished from its congeners by its *blowing.* If the water is smooth, the first part observed is the hump, projecting two or three feet above the surface; at very regular intervals of time, the snout emerges, at the distance of forty or fifty feet; from the extremity of the snout the jet is thrown up, and when seen from a distance, appears thick, low, bushy, and of a white colour. It is formed, according to Mr Beale, by the air expelled forcibly through the spiracle, acquiring its white colour from minute particles of water previously lodged in the external fissure. It is projected at an angle of 45°, in a slow and continuous manner, for about three seconds, and may be discovered at the distance of 4 or 5 miles. This leviathan is, like the mysticetus, remarkably timid, and is readily alarmed by the approach of any unlooked-for object. When frightened it is said by the sailors to be " gallied," probably galled; and in this state it performs many actions in a manner very different from the usual mode. One of these is what is called " sweeping," which consists in moving the tail slowly from side to side on the surface of the water, as if feeling for any object that might be near. This whale has also an extraordinary fashion of rolling over and over on the surface, especially when harpooned; in which case it will occasionally coil an amazing length of rope around it. But one of its most surprising feats—as it is of those of all the larger genera—is leaping completely out of the water, or " breaching," as it is called;—a practice which, from its dangerous results to those around, is regarded by mariners as far " more honoured in the breach than the observance." The mode in which this appears to be done is by descending to a certain depth, and then making several powerful strokes with its tail, thus imparting great velocity to the body before it reaches the surface, when it darts completely out of the water. It seldom breaches more than twice or thrice at a time, and in quick succession; the performance may be seen at the distance of six miles from the mast head. We once witnessed a Scotch whale performing a similar feat in Loch-fine, between the loved shores of Minard and Castle Lachlan.

The sperm-whale seems now to have nearly vanished from the northern hemisphere, though it is frequent in numerous places in the southern. In the year 1791, seventy-five vessels belonging to Britain were engaged in the trade, whilst in 1830 only thirty-one ships were sent out, all from the port of London, with an aggregate burden of 11,000 tons, and 937 men. On its introduction into commerce *spermaceti* was chiefly employed in medicine, in which its use is still continued; and it is also freely used in the cosmetic art. Its largest and most valuable application, however, has long been in the manufacture of candles, in which it maintains a rivalry with wax, as cheaper and not less elegant.

---

[1] *Oss. Fossil.* t. v. p. 339.

[2] For a somewhat minute and valuable account of the anatomy of a sperm-whale, which was cast ashore on the Yorkshire coast in April 1825, see a paper by James Alderson, Esq. in the second vol. of the *Trans. of the Cambridge Phil. Soc.*

[3] *Observations on the Natural History of the Sperm-Whale.* Lond 1835.

Ambergris, according to its quantity, is a peculiarly valuable product of the sperm-whale. The majority of sperm-whales, however, do not yield it. Sometimes it sells in London at about L.1 an ounce, but frequently two or three voyages are accomplished, and successfully too, without any ambergris being obtained. It is seldom or never found in young fish, but only in those of full size, or rather of great age. It is generally considered the result of some diseased process in the intestinal canal; the quantity obtained, therefore, is very various. Sometimes 50 lb. have been extracted from a single individual. Ambergris is frequently found in considerable quantities on the sea-shore, especially in the Indian seas. It is highly esteemed by the orientalists. With us its use is confined almost wholly to the perfumer.

C. sulcatus? Abel Rémusat. Lacépède. Reported to have a furrow below the lower jaw, and to frequent the Chinese seas.[1]

Aggadachgik? Tschicduk? Tschumtschugagah? Pallas and Chamisso. These are alleged Kamtschatkan varieties. See Less. and Fr. Cuv.

GENUS BALÆNA, Lacép. Cuv. Less. The *right-whale* of northern fishers. No teeth; blow-holes double; no dorsal fin; long whalebone or baleen in the upper jaw; blubber thick and highly productive of oil.

B. mysticetus, Linn. Desm. (No. 798.) *True whale*, Bon. Lacép. *Greenland whale* of Fab. and of fishers. *B. borealis*, Klein. (See Plate XVII., figure 12.) Length about 60 feet; body of vast circumference; fanons more than 300 on each side of upper jaw, extending from 10 to 15 feet in length; colour black above, and partly white beneath. Vertebræ 7, 13,—?[2]

In former times there was much exaggeration as to the dimensions of this whale, 80 and 100 feet being assigned as a frequent size, and 150 and 200 feet as not uncommon. Some of the ancients stated, that it attained even a much greater length. From the researches, however, of Dr Scoresby, it seems irrefragably established, that the mysticetus never exceeds nor has exceeded 65 or 70 feet.[3] That excellent observer was personally concerned in the capture of 322 whales, not one of which exceeded 60 feet. It is thickest a little behind the fins, whence it gradually tapers in a conical form towards the tail, and slightly towards the head. The head is remarkably large, forming nearly one-third of the whole bulk. Its under part is flat, and measures from 16 to 20 feet in length, and from 10 to 12 in breadth. When the mouth is open it presents a cavity as large as a small apartment, and capable of containing a ship's jolly-boat full of men.

The mysticetus has no dorsal fin, the pectoral fins are about nine feet long and five broad. The tail is semilunar, indented in the middle. On the most elevated part of the head, about sixteen feet from the extremity of the jaw, are situated the blow-holes, consisting of two longitudinal apertures, similar to the holes in the body of a violin, from eight to twelve inches in length. The mouth, in place of teeth, contains two extensive rows of baleen, commonly called *whalebone*, suspended from the upper jaw and sides of the crown bone. The plates are generally curved longitudinally, and give to the roof of the mouth the form of an arch. They inclose the tongue between their lower extremities, and are themselves covered by the lower lip. There are upwards of 300 of these plates on each side of the jaw; they are longest in the middle, whence they gradually diminish away to nothing both in front and behind. The tongue is incapable of protrusion; and the throat is remarkably narrow,—according to Sir C. Giesecké, not exceeding an inch and a half in width. The colour of the true whale is mostly velvet-black, with white in some parts underneath, and a tinge of yellow. The blubber, constituting the most valuable part of the animal, forms a complete wrapper round the whole body from eight to twenty inches thick.

Being somewhat lighter than the medium in which it swims, the Greenland whale can remain on the surface with its spiracles above water, without any effort or motion; and it is thus sometimes found asleep upon the waves. Though bulky and clumsy, it is capable of making great exertion. A whale extended motionless on the surface can sink, in the space of five or six seconds, beyond the reach of its human enemies. Dr Scoresby has observed a whale descending, after it had been harpooned, to the depth of a quarter of a mile, with the average velocity of seven or eight miles an hour. The usual rate, however, at which they swim when on their passage from one station to another, seldom exceeds four miles an hour. Sometimes they leap entirely out of the water, and sometimes they throw themselves into a perpendicular position, with their heads downwards, and waving their tremendous tails on high in the air, beat the water with awful violence,—the sound reverberating to the distance of two or three miles. This feat is denominated "lob-tailing." They usually remain at the surface to breathe, about two minutes—seldom longer; and during this time they blow eight or nine times, and then descend for an interval usually of five or ten minutes, although sometimes, when feeding, of fifteen or twenty. When harpooned or apprehending danger, the period is greatly prolonged. The food of these animals, so vast and strong, is too remarkable not to claim a moment's attention. They have no teeth, and hence we at once perceive that they cannot prey either on the smaller of their own kind or on fishes; and their throat is so narrow that they could scarcely dispose of such a morsel as might be swallowed by an ox. Their well provided pasture grounds, however, exhibit to the contemplation of the curious one of the most wonderful manifestations of beneficence and power. Vast portions of those spaces in which the whale is found, consist of what is called green-water; as there is yellow and red water, in other parts of the ocean. This was examined by Captain Scoresby in 1816, and to his astonishment he found that it obtained its colour from the presence of countless millions of animalcules, most of them invisible without the aid of the microscope, and of which the greater number consisted of a species of medusa. These minute creatures are not the immediate food of the whale; they form, however, the prey of the various shrimps, small crustacea, cuttle-fish, &c. upon which the monster of the deep is supported. When this whale feeds it swims with considerable velocity below the surface, with its jaws widely extended. A stream of water consequently enters its mouth, and along with it large quantities of minute crustaceous and molluscous animals; the water flows out again at the sides, but the food is entangled by the baleen or whalebone, which, from its compact arrangement, and thick internal covering of hair, does not allow a particle to escape, even of the size of the smallest grain. The mysticetus, though often found in great numbers, can scarcely be said to be gregarious;

[2] Giesecké.

[3] *Edin. Phil. Journ.* vol. i.

for it generally occurs either solitary or in pairs, except when attracted to the same spot by an abundance of palatable food, or a choice situation among polar icebergs.[1]

B. Nordcaper ?, Anderson, Bon., Lacép., Desm. (No. 799.) *B. glacialis ?*, Klein. We reject this species, as established by mistake on insufficient grounds.[2]

B. antarctica, Delalande, Cuv., Desmoul., Lacép., Fr. Cuv. Usually from forty to fifty feet long; colour wholly black; line of the forehead more depressed than in the *mysticetus*; pectorals longer and more pointed. Vertebræ 7, cervical, all anchylosed, 15 dorsal, others 37, in all 59. This species, nearly up to the present period, has been confounded with the preceding and probably we might have been still ignorant of the difference, had not M. Delalande, during his residence at the Cape of Good Hope, prepared one of these animals, and transmitted its skeleton to France, where Cuvier soon detected its specific characters. The whale of the Southern Seas is decidedly smaller than that of the north, measuring only from thirty-five to forty-five feet, though sometimes extending to fifty. Its baleen, owing to the great curve of the upper jaw, appears to be relatively longer, usually reaching to about nine feet in a fish of forty feet. Whilst the pectoral fins appear longer and more pointed, the lobes of the tail are less marked than in the preceding species. This whale is found in the bays of Terra del Fuego, and on the western coast of South America; it also occurs around New Holland, as well as along the African shore. It visits the Cape of Good principally in June. Its capture is more easily achieved than that of the great Greenland species.

The ensuing quotations seem to us to indicate the existence of other still undetermined species in the Arctic Regions. "The whales," says Dr Scoresby, "seen in the spring in lat. 80° N., which are usually full grown animals, disappear generally by the end of April. Those in 78° are of a mixed size; such as resort to fields in May and June are generally young animals. Those seen in 76° are almost always of a very large kind. In some the head measures four-tenths of the whole length, in others scarcely three-tenths; in some the circumference is upwards of seven-tenths of the length, in others less than six-tenths. It is probable the difference in the appearance of the heads, and the difference of proportion existing between the heads and bodies of some mysticetæ, are characteristic of different species or subspecies. Those inhabiting lower latitudes have commonly long heads and bodies compared to their circumference, moderately thick blubber and long whalebone; those of the mean fishing latitudes, that is 78° or 79°, have more commonly short broad heads, compared with the size of the body."[3] "It is certain," observes M. Frémenville, "that the fishers confound many species which are still unknown. On my expedition towards the North Pole, in 1806, I remarked there were great differences in the shape of the tails of the whales which were taken, and which, without doubt, belonged to species not yet accurately ascertained." It is also more than probable that another occurs in the southern seas. "I am certain," says Baron Cuvier, "that at least a third species exists at the Cape of Good Hope, seeing we have satisfactory knowledge of vertebræ, which, with the characters of the subgenus (without dorsal-fin), present also distinct specific characters."[4]

B. Gibbosa ? Bon., Lacép., Desm., No. 801. *Scrag-whale* and *Hunchback* of Dudley and the English; *B. à bosses* of the French; *Knoten-fisch* of the Germans, and of Anderson.

B. Nodosa ? Gmel., Bon., Lacép., Desm., No. 800. *Humpback whale* of Dudley and the English; *Pflockfisch*, Anderson, Crantz, &c.

We cannot pass by these alleged species, so long and widely recognised, without a few remarks. They are classed together as subgenera of the *true whale* by Lacépede, Desmarest, and many others, whilst Bonnaterre associates them with the *Gibbar*. Cuvier throws doubts on the existence of all these species, remarking that their right to a place is founded upon some obscure passages of Mr Dudley's paper in the Philosophical Transactions. The *humpback* of Dudley (*B. nodosa*) should evidently be removed from the true whales, because, according to Dudley himself, it is a rorqual: "the humpbacks have longitudinal reeves from head to tail on their bodies and sides, as far as their fins, half way down their body."[5] The *Gibbosa*, again, he remarks, comes nearest the true whale in figure and for quantity of oil; and, according to Anderson, it produces as much oil as the Greenland whale. Though we cannot accurately characterize this *Gibbosa*, neither can we altogether reject it; and the following facts supply something like additional evidence of its existence. Captain Day, a most respectable southern fisher, mentions that he occasionally took humpbacks as well as sperm whales and finners;[6] and Captain Weddell also states that he met with humpbacks, besides sperm whales and finners.[7] Captain Colnett, likewise, whose voyage was undertaken to increase our knowledge of the southern fishery, and who had many whalers among his crew, familiarly speaks of the humpback, as well as of the other kinds; and humps are described by M. Abel Rémusat and Lacépède as occurring on the heads of the *Punctata* and *Nigra*, two alleged Japanese species. We hence infer that attention should still be directed to the kind called *Gibbosa*.

B. Japonica ? Rémus., Lacép., Desm., No. 802. Less.

B. Lunulata ? Rémus., Lacép., Desm., No. 803. Less.

These species are described by Lacépède in a paper read to the Institute in 1818, from Japanese designs communicated by Rémusat, and the characters are detailed in the *Mem. de Mus. d'Hist. Nat.* t. iv. 473. Their existence, however, is very doubtful.

B. Kulcomoch ? Pallas, Chamisso, Less., Fr. Cuv.

B. Ischikagluch ? Pallas, Chamisso, Less., Fr. Cuv.

Pallas describes these species of the Kamschatkan Seas with apparent accuracy in his *Zoograph. Rosso Asiatica*, as does also Chamisso, the naturalist of the Rurick.[8] They are, however, far from being satisfactorily established.

B. Physalus ? Lin. *B. Gibbar*, Bon., Desm., No. 804. *Physalis*, Scoresby. *Balænoptera Gibbar*, Lacépède. *Finfisch*, Anderson; *Razor-back* of whalers. Fin on the back, and no pectoral folds. There are no sufficient grounds for the admission of this supposed species, which seems to have arisen from some confusion with the rorquals.[9]

Genus Rorqualus,[10] Cuvier., Less., F. Cuv. (See Plate XVII., figure 13.) No teeth; a dorsal-fin; folds under the throat and chest; fanons in upper jaw, but short;

---

[1] We cannot dismiss these slight notices of this important species, without referring the reader to Dr Scoresby's elaborate treatise on the *Arctic Regions*, which contains a most interesting history and description of the northern whale-fishery. Consult also the first volume of the *Edinburgh Cabinet Library*, entitled *Narrative of Discovery and Adventure in the Polar Seas and Regions.* Fourth Edition, 1835. We may further add, that the first tolerable figure of *B. Mysticetus* ever published was the capital one of Scoresby.

[10] *Rorqual* in the Norwegian tongue means *whale with folds.*

blubber not thick, nor yielding much oil; blow-hole double.[1]

R. borealis, Less. *R. Boops*, Fr. Cuv. The *Great Northern Rorqual, Balæna Rorqualus*. Bon., Desm. No. 806. The general form of the body is that of an immense cylinder, largest at the head, and gradually diminishing to the tail; dorsal small, obtuse at the summit, placed opposite the vent; pectorals thin, straight, and pointed at the extremity; blow-holes not situated on the most elevated part of the head, but in advance of the perpendicular over the eye; the upper jaw descends rapidly towards the lower, is not so long, and much weaker; the baleen much shorter than in the mysticetus. Numerous folds cover the throat and chest, and extend to the abdomen. Colour black above, whitish underneath; inside of the folds pale red. Length from 100 to 110 feet. Vertebræ 7, 15, 42; = 64.

The northern rorqual is the largest of the whale tribe, the mightiest giant of the "great deep," and probably the most powerful and bulky of all created beings. Its head is to its entire length as one to four. It differs from the *mysticetus* in its body being proportionably longer and more slender, in its form being less cylindrical, in possessing a dorsal-fin, in its skin or blubber being much thinner (seldom exceeding six inches), and in its speed being greater, its action quicker, and more restless, and its conduct bolder. The blowing also is more violent, and its baleen much shorter and less valuable. The cause of this last important difference is very plain, and may be best illustrated by a glance at the accompanying engraving (see Plate XVII.), in which there is given a side view (figure 9) of the cranium of the mysticetus and (figure 10) of that of the rorqual. It will at once be seen that the upper jaw of the former is relatively larger, and much more curved; the intervening space in both is filled with baleen, which accordingly must be long in the mysticetus, and short in the rorqual, the longest laminæ seldom measuring four feet.

In Mr F. Knox's account of the great rorqual, we are informed that 314 plates were counted on each side; and that, on further examination, it was found that these invariably extended mesially only about fifteen inches, and were then succeeded by a vast number of smaller plates, which gradually became less and less, till finally they were converted into bristles; so that, correctly speaking, there were probably not fewer than 4000 or 5000 distinct plates of whalebone. This baleen, when recent, was highly elastic and soft, the fringed edge being as pliable as the hair on the human head, and thus forming a sieve of the most perfect kind. From the same source we also learn that the posterior arch of the palate was so large that it could admit a man, being thus like a great vestibule to the windpipe and gullet, which last was quite closed when first seen, and appeared as if it would admit with difficulty even the human hand.

The proper nourishment of this genus is not only the small medusæ, shrimps, &c. which form the food of the mysticetus, but also the medusæ of larger size, and substantial fishes such as herring, cod, and salmon. There seems no ground to question, that these whales often follow in the tract of various fishes, and devour them in quantities which it would not be easy to conceive. Thus M. Desmoulins states that *six hundred great cod, and an immense quantity of pilchards*, have been found in the stomach of a single rorqual.

The plicæ or folds from which the genus derives its name constitute a singular structure, the precise use of which has not hitherto been very clearly stated. John Hunter described it with his usual accuracy, and observed that it must increase the elasticity of the integuments of the part, but confessed he could not perceive wherefore this should be, or how it was made useful. Lacépède also particularly describes it, and it has since been generally noticed by subsequent authors. It consists of a number of longitudinal folds, nearly parallel, which commence under the lower lip, occupying the space between the two branches of the jaw, pass down the throat, covering the whole extent of the chest from one fin to the other, and terminate far down the abdomen. The external portion of these folds is of the colour of the neighbouring skin, whilst the parts which are infolded are of a more delicate hue, generally of a pale white, and in some species of a beautiful red colour. The simplest and probably the true account of the use of these folds is this: The rorqual has not, in the upper jaw, that large segment of a circle in which the *mysticetus* collects its food; but to compensate for this it has it in the lower; for, when it opens its prodigious mouth, the water rushing in opens these folds, and so forms a vast well, in which its supplies are collected. On shutting its mouth and contracting the folds the water is expelled, whilst the strainer formed by the baleen retains the captured fish, which, entangled as it were within the folds of an enormous net, become an easy prey.

This animal attains the vast length of from 100 to 110 feet,—Sir A. de Capel Brooke says 120,[2]—with a circumference of between 30 and 40, which is the same as that of the *mysticetus*. Dr Scoresby remarks, "that it seems apparently of the length of a ship, that is, from 90 to 110 feet;"[3] and it has more than once been actually measured at 105 feet. Its blowing is very violent, and may be heard in calm weather at a great distance. Though the species of this genus are sometimes at a distance mistaken for the mysticetus, yet their appearance and action are so different that they may be generally distinguished. They seldom lie quietly on the water when breathing, but usually move with a velocity of four or five miles an hour, and when they descend they very rarely throw up their tails into the air, which is the general practice of the other.

The rorqual occurs in great numbers in the Arctic Seas, especially along the edge of the ice between Cherie Island and Nova Zembla. Persons trading to Archangel have often mistaken it for the *right whale*. It is seldom seen amid much ice, and seems to be avoided by the *mysticetus*; and the whalers accordingly view its appearance with concern. It swims with a velocity, at the greatest, of about twelve miles an hour. It is by no means a timid animal. When closely pursued by boats it manifests little fear, does not attempt to outstrip them in the race, and merely endeavours to avoid them by diving or changing its direction.

---

[1] The prevailing arrangement of the individuals included under this genus has for many years been that of Bonnaterre and Lacépède. It contained,

1. *B. Jubartes*, Klein., Bon.; *Balænopter. Jubart*, Lacép., Desm., 805; *B. Boops*, Lin.
2. *B. Rorqualus*, Bon.; *Balænopter. Rorqual*, Lacep., Desm. 806; *B. Musculus*, Lin.
3. *B. Rostrata*, Fab., Hunter: *Balænopter. Acuto-rostrata*, Lacép., Desm., No. 807.

Cuvier considers these three, along with the *Physalus* (above alluded to), as one species. For reasons which will presently appear, we retain the *Rostrata* as distinct; but Cuvier's remarks in reference to the others are extremely judicious. "When we examine the figures and descriptions on which these species rest, it will be found that there are no means by which we can assign them distinctive characters. When we come also to examine in detail the testimonies respecting them, we find no person who has seen more than one of them, I do not say at the same time, but even in succession; and each author is obliged to support himself upon the testimony of another. Almost the only distinction we can make out is the size which may be the result of age; so that we are disposed to doubt and deny their existence as distinct."—*Oss. Fossil.* t. v. 365-6.

Cetacea.

If harpooned, or otherwise wounded, it exerts all its energies, flies off with the utmost velocity, and usually escapes. This great speed and activity render it a dangerous object of attack, whilst the small quantity of oil it yields makes it unworthy of the particular attention of the fishers. But though regular whalers usually decline the encounter, it is not so with the natives of the polar regions, whose wants compel them to make every exertion which promises the least success, and whose opportunities are frequently peculiarly favourable. Sir C. Giesecké states, in regard to the Greenlanders, that both men and women engage in the adventure,—the former in their keyacks, the latter in their bomiaks. The men in their light skiffs pursue the whale as closely as possible, and continue to throw as many harpoons and lances into him as they can, until he dies of loss of blood; and then all join their canoes, fasten to their spoil, and carry it home, when it is faithfully divided. In the words of the poet:

> Trained with inimitable art to float,
> Each balanced in his bubble of a boat;
> With dexterous paddle steering through the spray,
> With poised harpoon to strike his plunging prey;
> As if the skiff, the seaman, oar, and dart,
> Were one compacted body, by one heart
> With instinct, motion, pulse, empow'red to ride
> A human Nautilus upon the tide.

R. rostratus (see Plate XVII., figure 13), Knox. Lesson. *Balæna Rostrata*, Fab., Lin., Hunter, Des., 807, *Balænoptera acuto-rostrata*, Lacép., Scoresby.

This is the smallest of the genus, twenty-five feet being assigned as its extreme limits; fanons short and white, pectorals ovate, margins obtuse; dorsal over the vent; many deep folds under the throat and chest; colour black above, white beneath; interior of the folds red. For the undisputed establishment of this species we are indebted to the zeal and assiduity of Dr Knox. It is true that Fabricius described it with his accustomed elegance and precision; that Mr Hunter likewise met with and delineated it; and that Dr Scoresby's work contains an exact representation, supplied through Dr Traill. But notwithstanding all this, the details which were collected were so slight and meagre, that not only were much ignorance and error prevalent concerning it, but many naturalists (of whom Baron Cuvier, in 1823, was one, and Mr F. Cuvier, in 1836, was another) were led to doubt even its existence.

Dr Knox's specimen was taken in February 1834, near Queensferry, Frith of Forth. It was a young one, measuring only ten feet. On obtaining possession of it, Dr K. thought of suspending it horizontally, as in the posture of swimming. "By this means," he remarks, "the proper character of the head and mouth were given, and this so much altered the appearance of the animal, that the author thinks all previous views extremely incorrect, besides tending to mislead the naturalist as to the real capacity of the mouth of the genus, which is really very great. The lower part of the mouth is an enormous pouch or bag which, in the great northern rorqual, must at times contain an incredible volume of water."[1] We have yet to state how Dr Knox established the fact that the lesser rorqual ought to be considered as distinct. It was by means of the comparative osteology of the two species, which exhibited the following discrepancies:—

	Vertebræ.			
	Cervical.	Dorsal.	Remaining.	Total.
Great rorqual,	7	15	43	65
Lesser do.	7	11	30	48

Before laying aside Dr K.'s brief notice, we must introduce a few of his remarks. "Two bolster-like substances filled the blowing canals, which are drawn from them at the moment of breathing, by muscles provided for that purpose; the mechanism is admirable, and would sustain a pressure from above, though the animal were to descend thousands of fathoms." Again: "The cavity of the cranium, besides containing the brain and its membranes, inclosed also a very large mass of a vascular substance, closely resembling the erectile tissue: it filled a very large proportion of the interior of the cranium, extending from thence into the interior of the spinal column, three-fourths of whose cavity it also occupied, surrounding the spinal marrow and nerves." The olfactory nerves "were at least as large as those of man."

Cetacea.

The *R. rostratus* frequents the rocky bays of Greenland, especially during summer, and also the coasts of Iceland and Norway; sometimes, though rarely, coming into lower latitudes. In its habits it is very active, and its food consists of arctic salmon and of other fishes.

R. Mediterraniensis, Cuv.; *Balænoptera Mediterraniensis*, Less.; *R. musculus*, Linn., Lacép. Head remarkably rounded; upper jaw shorter than the lower; dorsal fin smaller, situated four-fifths down the body, and much beyond the vent; the folds extend to the vent; upper parts of the body bluish-black, gradually declining on the flanks, and giving place to a dull white beneath. Vertebræ, 7. 14. 40? = 61? For the specific character drawn from the osteology, see *Oss. Fossil.* t. v. 370. This species is not uncommon in the Mediterranean. One, seventy-five feet long, was stranded near St. Cyprien, Eastern Pyrenees, in 1828.

R. antarcticus, Cuv., Fr. Cuv., Delalande; *Balænoptera australis*, Less.; *Poeskop* of the Dutch at the Cape. Dorsal long and situated directly over the pectorals; a hump upon the occiput; the colour black above, and pure white beneath; the furrows under the throat and chest of a lively rosy hue. Vertebræ, 7, 14, 31; = 52. For specific characters of bones of the cranium, see *Oss. Fossil*, v. 372.

As we have seen that there is a *mysticetus* of the southern as well as northern seas, so within the last few years it has been established that there is an antarctic as well as an arctic rorqual. These discoveries recall to mind an observation of Buffon's, already more than once referred to, that every great division of the globe has animals peculiar to itself. It is true this law has not often been demonstrated in reference to the inhabitants of the ocean, although it has been alleged that the intertropical zone includes the same species throughout its whole circumference, and that as we remove from it, both northwards and southwards, each parallel has its peculiar kinds, of which the limits are terminated by the different meridians of the globe. In the present state of our knowledge, it would be going too far to affirm that none of the Cetacea plough their watery way through every clime; but Dr Scoresby decidedly states that the true Greenland whale has never been seen in European seas; and since the time that this startling statement was made, all later discoveries have greatly tended to confirm the views of the eloquent though not always accurate Buffon.

The southern rorqual but rarely approaches the coasts at the Cape, since it is stated that only two or three are observed there during the year; nor does any one think of pursuing it, since its great power and velocity make it not only difficult but dangerous of capture, and its produce by no means repays either the risk or labour.

Balænoptera Abugulich?; B. Mangidach?; B. Agamachthick?; B. Aliomoch? Pallas and Chamisso. These four are alleged species of Kamtschatka. See Lesson and Fr. Cuvier's works.

---

[1] *Proceedings of the Royal Society of Edinburgh*, 1834.

Balænoptera punctulata?; B. nigra?; B. cœrulescens?; B. maculata? Rémusat, Lacép. The species just named are supposed Japanese whales, of which we certainly know little else than the names.[1] Less., Fr. Cuv.

We have now reviewed forty-nine species which appear to be established, eighteen which are probable, and thirty-three which are extremely doubtful; and having thus completed our proposed summary of the Cetaceous tribes, we shall conclude by presenting such observations on their *comparative anatomy* as may not be inconsistent with the plan of the present treatise. We shall confine ourselves to a few of the most important and peculiar parts of structure.[2]

The most striking feature in the economy of the Cetacea is, that they are Mammalia, and yet inhabitants of the ocean. We do not now refer solely to their being viviparous, whilst fish on the contrary are oviparous, though this, unquestionably, forms a very marked distinction; but, more especially, to their being warm-blooded animals, and to their discharging the all-important functions of the sanguiferous system not through branchiæ, but by means of lungs,—thus breathing like quadrupeds, whilst their appropriate element is the watery deep. Hence it is that they occupy so singular a position in the classification of the animal kingdom. Whilst they inhabit the water like fishes, and while in their mode of progression through their common element, and in some of their more obvious external characters, they seem to claim kindred with the other inhabitants of the deep, yet in every essential respect they are unequivocally marked as members, not of the last class of the Vertebratæ—that of fish, but of the first and most remote class—that of the Mammalia. Fish are produced from spawn, and after the lapse of weeks or months, emerge from their slimy beds of weed or gravel, where they had long lain neglected by their oblivious parents; but whales are brought alive into the world, and the cub is nourished for months by its mother's milk, and disports itself around her in playful affection, gambolling through the green translucent sea, like the fawn or the lambkin rejoicing in their sunny glades. Fish, again, are cold-blooded, their circulating fluid being only exposed to the water through the medium of the gills; but the whale has no gills, nor any thing resembling these organs; on the contrary, it has true lungs, in a great bony chest, into which the air is freely admitted, not indeed by the mouth, but by a peculiar apparatus to be presently explained, and through which it breathes the pure air of heaven like other Mammalia, and is thus enabled to maintain an extremely high temperature of body even in the midst of icy seas. Finally, fish never breathe, and if removed from water, and brought into air, they almost immediately expire; whereas the Cetacea, if deprived of air, and confined beneath the surface, are speedily and literally drowned.

It is this constant demand for vital air, and the consequent necessity under which they labour of coming to the surface to perform the function of *respiration*, which have procured for them the distinctive appellation of *Blowers*: and it is this same necessity which affords, in fact, the explanation of all the peculiarities of their structure. In most of the Mammalia, the inhalations succeed each other with great rapidity, and cannot be suspended for more than a few instants. In man, for example, even when at rest, they occur every three seconds, whilst the interval in the Cetacea is augmented many hundred and even thousand fold; for nearly all the whales can remain under water for a quarter of an hour or twenty minutes, and the larger genera for an hour and sometimes nearer two. But respiration is subservient mainly to the circulation of the blood; and the singular and anomalous fact just alluded to, is enough to prove that there must be some grand peculiarity in their sanguiferous system. This peculiarity has indeed for many years been recognised, but without its true use having been stated or understood. We may remark, then, that in the Cete there exists a great reservoir for arterial blood; and that when they come to respire on the surface, besides simply filling the chest with air, they likewise fill this reservoir with highly purified and arterialized blood. This reservoir consists of an innumerable congeries, *a vast plexus of great arteries*, which is lodged beneath the pleuræ, between the ribs, all round the spinal column, and even within it, as within the cranium itself. The vessels forming this plexus rise chiefly from the upper intercostal, and other great vessels near the heart; and they are found not connected by close and frequent ramifications, which anastomose freely with each other, but to a great extent they may generally be followed out and unravelled, as if they were a set of vessels twisted a thousand times upon themselves: nor do they appear to communicate directly with any veins; and hence it is inferred that after the blood from the lungs is vitiated, the pure fluid from this reservoir finds its way gradually into the general circulation, and thus for a long period maintains life. This structure was first noticed and accurately described by John Hunter.[3] Dr Barclay then described it as existing within the spinal canal of the beluga,[4] and Dr Knox more recently observed it within the cranial cavity itself of the rorqual;[5] Messrs Desmoulins and Breschet have since noticed it in France; and to these latter naturalists, we believe, belongs the merit of associating this very peculiar structure with the no less extraordinary anomaly in the respiratory function of the order, in the manner we have now attempted to explain.[6] Desmoulins likewise states that the temperature of the blood in whales is 104°, which is considerably higher than in most of the Mammalia.[7]

But while the Cetacea breathe on the surface of the water, it is equally true that they feed beneath it, and as the access of water into the lungs would be as destructive to them as to ourselves, we at once perceive that some peculiar apparatus is required whereby, when freely swallowing, water may be prevented from entering the lungs. This is effected by the peculiar structure of the *wind-pipe*. In man and the other Mammalia, the mouth and nostrils terminate posteriorly in a common pouch or bag, called the pharynx, from which both the windpipe and gullet take their origin;—the former and anterior, through an aperture called the glottis, covered by the epiglottis as a valve, which usually stands erect, but upon the passage of the food shuts down like a lid, and so leaves the posterior opening free. In the Cete, the blow-holes admit free ingress and egress of air into and from the lungs; but as the mouth is at the same time usually filled with water, a mechanism is provided to prevent the fluid from rushing with the air into the chest. The epiglottis, then, instead of being a simple and usually unshut lid, is in the Cetacea a projecting tube. In the shape of this tube there is great variety in the individual species; and as an example merely, we refer to sketches (Plate XVII., figures 3 and 4), which exhibit the larynx in the common dolphin (as shewn in the *Encyclop. Methodique*), and in the narwhal (as represented by Dr Fleming);[8] in both of which it will be observed that the rima glottidis is on the summit of a projecting cone or pyramid. This cone is received into the lower end of the blowing-*tube*, a circular aperture, surrounded with a strong sphincter muscle which includes the glottis in its grasp, thus uniting the wind-pipe and blow-tube, which cross the fauces and divide it into a kind of double vestibule. This union, however, does not appear to be fixed and permanent, so that we see no reason to conclude, as has been done, that the parts are not under the power of the will, and that the larynx cannot at pleasure be withdrawn from the blowing canal.

This is a physiological point of considerable importance, as on it depends the solution of the question now agitated regarding what forms the proper substance of the *jets d'eau* of the whale. We have already stated that the larynx enters into the lower aperture of the blowing-tube, the spiracle considerably enlarges immediately above this aperture, and proceeds upwards and forwards, through the bones and soft parts, till it reaches the summit of the head. The tube is usually divided by a septum into two canals, which in the greatest whales open by two blow-holes, whilst in all the smaller the septum ceases, and the spiracle terminates as it begins by a single aperture. It was long supposed that the liquid discharge of the spouting, was chiefly owing to the water which the Cete take in with their food, and which, if swallowed, would only incommode them. But in opposition to this, it has recently been maintained, that the proper egress of the water is the same as its ingress, and that by contracting the surrounding muscles, the throat and mouth can easily be cleared of fluid. The spiracles, moreover, have a secretion peculiar to themselves, and it is now the prevailing opinion among naturalists, that it is chiefly this secretion, together with the superfluous vapour of the lungs, which, along with the expired breath, forms the proper substance of the projected column. We venture, however, to express our doubts whether this point is either definitely or satisfactorily established. It would appear that there is an allowed difficulty arising from the great quantity of the fluid frequently expelled. This is met by the statement, that sometimes the ejected air comes in contact with the supernatant water, and raises quantities along with it. With perfect cognisance of these opinions, however, we find that M. Lesson, from much personal observation, dissented from the previously prevailing view, and, as late as 1828, maintained the old and now often-scouted opinion. He stated that from having often seen the phenomenon, and frequently within the distance of a few yards, he felt constrained to oppose the modern hypothesis. Drs Quoy and Gaimard, though they allow that sometimes no water is expelled during expiration, yet having often observed that during stormy weather the jets took place both more frequently and more abundantly, account for the fact on the supposition that, as it is then the Cetacea feed most freely, the projection of the water takes place chiefly when they are engaged in this important process. Desmoulins expresses his opinion thus: "It is not water, but mucosity, which is expelled by the blow-holes during expiration; the animal spouts water only after deglutition, or in moments of rage." This twofold view of the matter we are disposed to consider as rather feasible; and in the meanwhile we may remark, that as the mechanism is different in almost every genus, so the character of the blowing also differs greatly,—indeed to such an extent, that an experienced observer can, we believe, even at a distance determine the species at any time during day-light; the utility of which to the whalers need not be insisted upon.

The blow-holes are very extensive apertures, being not less in the larger genera than a foot in length. This is not more than sufficient when the animal is breathing upon the surface of the water; but a new train of thought is suggested when we reflect that the whale often descends to the depths of the ocean, and thus endures a pressure which can scarcely be conceived, amounting according to Dr Scoresby to 154 atmospheres, or about a ton upon every square inch. How then is this pressure to be resisted, and the water prevented from entering the lungs, and thus destroying life? This is effected mainly by *a set of valves* which act upon the same principle in all the genera, but which are varied in each by a number of contrivances equally beautiful and efficient. We shall illustrate this remark, by epitomizing a short portion of Pallas's excellent account of the apparatus in the white whale. The blow-hole opens in the most elevated part of the head, and this opening is circumscribed by a double arch. The skin is drawn towards the orifice, and forms upon it a soft papillary valve, which prevents the entrance of all foreign matters. The skin over the valve is scarcely two lines thick, but internally it envelopes a projecting body, which is about two inches thick, and is composed of a net-work of tendinous fibres hard as wood, and scarcely capable of being cut with a knife. A similar net-work of tendinous fibres, arranged in circles, forms, in this situation, the external wall of the spiracle; and two strong muscles rising from the frontal bone, and peculiar to the tube, acting on these bodies, most effectually shut them down, and so secure the canal. A similar valvular apparatus exists over the *meatus auditorius* in those species in which it is open, and not covered, as it is in most, with a strong and impenetrable membrane.

This leads to a few remarks on the *skin*, or general external covering, which is often subjected to such inconceivable pressure. The integuments, though soft and flexible like the finest velvet, are so curiously constructed as to enable them to present the most effectual resistance. We say nothing of the *epidermis*, with its mucous-oily covering, nor of the *rete mucosum*, but proceed to what are regarded as two layers, viz. the *cutis vera* and the lard or *blubber*, the former of which is represented as thick and strong, and the latter is held to correspond with the subcutaneous fat in other animals. This is the view that naturalists in general, influenced probably by analogy, have taken; it is espoused by Ray, Tyson, Pennant, Hunter, Scoresby, Cuvier, &c. But we believe that, according to this account, the great peculiarity of the structure is disregarded, and the essential character, so much desiderated, is overlooked. According to Pallas, Giesecké, and Professor Jacob, there is no distinction between the true skin and the blubber, and the whole is nothing more than modified skin. The structure, upon close examination, is found to consist throughout of an interlacement of tough fibres, crossing each other in every direction, as in the *cutis vera*, but having a somewhat more open texture, to afford room for the oil. Had the integuments consisted chiefly, as is usually stated, of a soft wrapper of common fat, though it had been double in thickness to that usually found in whales, yet it could not have so well resisted the superincumbent pressure; whereas, by its being wholly a modification of the true skin, always firm and elastic, and in this case never less than several inches, and sometimes between one and two feet thick, it operates like so much caoutchouc, and possesses such density and elasticity that the more it is pressed it resists the more.[1] Other uses of this peculiarity of the skin will readily suggest themselves. The order is warm-blooded, and yet is exposed to the keenest cold, in the most remote recesses of the frozen seas. Hence this wrapper or blanket, as it is appropriately called, being a bad conductor of caloric, will at once resist the surrounding cold, and retain the animal heat. On this account such an integument would seem to be essential; but its bulk and quantity are enormous,—sometimes weighing thirty tons. This might appear sufficient to overwhelm the animal; but, on the contrary, the fatty mass being specifically lighter than water, instead of oppressing its owner, buoys it up,—thus making it relatively lighter and more active.

---

[1] For MM. Breschet and Rousset's account of the minute structure of the integuments of the whale, see *Magazine of Zoology and Botany*, vol. i. p. 181.

But we must conclude these interesting generalities by a short reference to the *brain*. It would appear that the observations made on this organ are by much too few to enable us to come to anything like general results; and in systematic writers we meet with the utmost contrariety of statement. Thus Cuvier, judging from the limited opportunities he had then enjoyed, speaks of the brain of the Cetacea generally as distinguished for its great breadth and height;[1] whilst M. Lesson, on the other hand, states that it is always very small in relation to the size of the animals.[2] Dr Scoresby states, that in a young *B. mysticetus* which weighed 11,200 lb., the brain weighed only 3 lb. 12 ounces, which is only $\frac{1}{3000}$th part of the whole animal. In a young *R. rostratus* which measured 17 feet, Mr Hunter found that the brain weighed 4 lb. 8 ounces; and M. Delalande stated that in a *Rorqual* nearly 80 feet long, the brain measured only 13 inches by 9. On the other hand, Cuvier states, from five examinations of the porpoise and dolphin, that, on the average, the brain weighed $\frac{1}{63}$d part of the whole. This statement regarding these smaller groups is corroborated by Tyson and Ray; and Tiedemann, the highest modern authority in this department, remarks: "That the brain of the dolphin is distinguished from that of monkeys by its great size and development, and next to the brain of the orang-outang, approaches nearest in this respect to that of man." From these data it would follow, that the organ is very large in the smaller groups, and very small in the larger. We insert (Plate XVII., figure 7) a sketch of Tiedemann's plate of the base of the brain in the dolphin; and may add that, considering the marked effect which the relative size of this important organ generally produces on the character of the animal, it seems desirable that every opportunity should be embraced to accumulate accurate information on the subject.

Let it be borne in mind by the rising race, that in relation to the cetaceous tribes, an enterprising naturalist of accurate habits, well versed in the recorded observations of his predecessors, and at the same time inclined to original investigation, has still before him a vast, and in several of its departments, an almost unexamined field. We here close our account of the class Mammalia. (J. W.)

MAN, the noblest of all earthly creatures, stands related, on the one hand, through his body, to the world of matter, and on the other, through his mind, to the world of spirit. For until it can be established inductively that the modes of extension and the modes of thought are alike ultimately referable, as some have alleged, to one common substance, the laws of a sound philosophy demand the ascription of the one class of phenomena to one substance termed *matter*, and of the other class of phenomena to another substance termed *mind.* With his sensuous nature binding him fast to the present world, and his moral and religious nature raising him towards God,—at the verge of the animal kingdom most remote from its point of contact with the kingdom of organic life, yet the occupant of that other kingdom of pure intelligence where the conscience asserts its authority and dispenses its awards,—man, the only representative of the order *Bimana*, the μέροψ, the *voice-dividing*, the creature of speech, and possessor of the higher reason, stands really where he was first placed—at the head of all earthly creatures, the sole lord of the creation. From this duality of man's nature there results the two-fold division of the human sciences into *mental* and *physical.* In the former we consider man as a being capable of knowing and doing; in the latter, as a portion of organized animal matter. The mental sciences are distributed into LOGIC, METAPHYSICS, LANGUAGE, MORAL PHILOSOPHY, and THEOLOGY. In LOGIC we study the laws of thought as thought; in METAPHYSICS we either study the faculties, operations, and laws of the mind, viz., *Psychology*, or inquire into the nature of being as distinguished from phenomenon, viz., *Ontology;* in LANGUAGE we view man as capable of speech, of forming articulate sounds expressive of his thoughts and feelings; in MORAL PHILOSOPHY, or Ethics, we regard him as a responsible agent, and inquire into the nature of human duty in all its relationships; in THEOLOGY and MYTHOLOGY, again, we deal with man as a creature endowed with a religious sense—as a being capable of worship. The physical sciences which refer directly to man are ETHNOLOGY, ANATOMY, and PHYSIOLOGY. In the first we consider man as an object of natural history; in the second we investigate the structure of his body; and in the third we study the doctrine of its vital phenomena.

These branches of knowledge regard man chiefly in his normal condition. For the abnormal or diseased state of man's mind, see MENTAL DISEASES; and for the abnormal or diseased state of his body, see MEDICINE, &c.

MAN, ISLE OF, lies between N. Lat. 54. and 55., W. Long. 4. and 5.; the centre of the island being in N. Lat. 54. 16., and W. Long. 4. 30. It extends lengthwise in a N.N.E. and S.S.W. direction about 31 miles, and varies in breadth from 8 to 12 miles. Its circumference, without following the indentations of a very irregular shore, is about 75 miles; its area contains 209 square miles, or 140,447 statute acres, 30,000 of which are mountains and commons. The island is situate nearly mid-channel in the Irish Sea, about equidistant from England, Scotland, and Ireland.

The outline and aspect of the island is thus described by the Rev. J. G. Cumming of Lichfield:—"The *northern* view is a narrow track of almost level land (which is an almost plane area of 50 square miles), surrounded by an abrupt pile of mountains, rent in chasms, forming the lovely glens of Ravensdale, Sulby Glen, Glen Aldyn, and Ballure. The *western* view is that of an extended pile of mountains, descending rapidly to the sea on the nearer side, distinctly precipitous at the south-western extremity, intersected at right angles by the two valleys of Port Erin and Peel. The *southern* view is that of a gradual slope from the sea-level to the highest points, without any distinct valleys, but occupied by towns, villages, villas, cottages, corn fields, and pastures. The *eastern* view (as presented on approaching from Liverpool) is that of a succession of bold cliffs and headlands, backed at a distance of 7 or 8 miles by mountains, ranging from 1500 to 2000 feet high, between which and the cliffs the slope is generally easy, and clothed with verdure. From the intersection of the Douglas valley at the centre, and the Straits of Kitterland at its southern extremity, separating the Calf Isle from the mainland, it appears as if divided into three distinct portions. Another peculiarity is, that as the vessel approaches the island, it appears *suddenly* lengthened to the extent of 6 miles at its northern extremity. This is caused by the low, level tract of land extending from the foot of the mountain chain to the Point of Ayre; and being only a few feet above the sea-level, it is the last portion to appear and the first to disappear, according as the spectator may approach or recede."

The mountain chain, which forms the most prominent feature on its surface, intersects the island in an oblique direction, and extends from Marughold Head to the Calf Islet, comprising within its range Sneafield, North and South Barrule, Bein-y-Phot, Greebah, and many others. The highest summits are Sneafield and North Barrule, the former being 2036, and the latter 1854 feet above the level of the sea. The sides of the mountains are clothed with turbary, moss, and heath. The whole chain, beginning with North Barrule, consists of clay schist (lower silurian), which is also the prevailing formation in South Barrule (1592 feet), the latter being varied on the eastern side with large masses of granite containing silvery mica, red and white felspar, and grey quartz. Greebah is 1600 feet above the sea-level, and is rugged and precipitous, especially on its southern side, towards the Douglas and Peel road. Bein-y-Phot (1784 feet) is marshy, and even in summer the ascent is tedious. The other mountains of lesser note are,—Slieau-ny-Fraughane (1598 feet), Irey-ny-Lhaa (1445 feet), Slieau-ny-Carnaane (1449 feet), Slieu-Dhoo (1139 feet), Slieau-Whallin (1068 feet), and Sartel, Slieau-Hearn, Slieau-Chiarn, &c. From Sneafield, which rises in the southern extremity of Ayre, in clear weather, one can descry the mountains of Cumberland and Lancashire in England, of Carnarvon and Anglesea in Wales, of Arklow and Morne in Ireland, and of Galloway and Dumfriesshire in Scotland.

The rivers of the island, though numerous, are all small in size. The Sulby, the largest, rises in the mountain group around Sneafield, and, after running 9 miles, discharges itself into the sea at Ramsey. The Neb, or Great River, has one portion of its tributary streams on South Baroole, and after being joined at Slieau-Aalin by a branch issuing from the western side of the mountains of Kirk German and Kirk Michael, joins the Irish Sea at Peel. The Silverburn, or Castletown River, has also two branches, the principal of which rises in the S. side of South Barrule, and, uniting with the other a little below Athollbridge, terminates its course in Castletown Bay. The Dhu, or Black River, takes its rise in the W. side of Mount Garrahan, and at about a mile from Douglas it receives the waters of the Glass, or Grey River, which rises in the mountain group of which Bein-y-Phot is the centre. The Laxey River descends from the eastern declivity of Sneafield, and terminates its course in Laxey Bay.

The following remarks on the natural history of the island were contributed by the late Professor Edward Forbes to *Kerruish's Guide to the Isle of Man:—*

"In common with Ireland, this island is exempt from venomous reptiles and toads, as neither serpents nor toads are found in it; but frogs are abundant, though they are popularly believed to have been imported, an idea for which there is no foundation. *Lacerta stirpium* (sand lizard), is common in the N.; and *Lacerta agilis* (common lizard), abounds in old hedges and dry banks in every part of the island. *Triton palustris* (warty eft), and *Triton punctatus*, (common eft), are by no means rare in their different habitats everywhere. Several of the more common of the four-footed English annoyances are absent, such as foxes, badgers, and otters. It is said that deer formerly inhabited the mountains, but they, like their great prototype, the fossil elk, have long since passed away. The only remarkable quadruped peculiar to the island, and of which it can boast, is the tailless cat, an accidental variety of the common species *Felis catus*, frequently showing no traces of caudal vertebra, and others a merely rudimental substitute for it. Of game birds, a few of the partridge and quail remain, but grouse is no longer to be found. Snipes are abundant. That rare bird the Manx puffin (*Procellaria anglorum*), formerly an inhabitant of the Calf, is now rarely found there. Of the rarer British land birds, the red-legged crow is common; the king-fisher scarce; and the hoopoe, the goatsucker, the shrike, the cross-bill, and the roller, have been killed on the island. Of sea-birds there is great variety. Many rare fishes, as might be expected, are found in the neighbouring sea. The entomology of the island is not attractive, though a few of the rarer coleoptera may be found on the sandy district of the N. Many scarce shell-fish abound on the coast, and on the banks which surround the island. It is not remarkably rich in plants, and probably does not contain more than five hundred species of the flowering kinds. Nevertheless, among them are several scarce species."

The following brief summary of the geology of the island was also furnished to the same work by the Rev. J. G. Cumming:—

"It is only of late years that the geology of the Isle of Man has attracted attention, and yet it is full of interest. The very large development of mineral resources, especially in the mining districts of Foxdale and Laxey; the value also of the quarries of granite, limestone, flagstone, ironstone, and marble;—gives a particular importance to the determination of the geological age of the strata of which the island is composed. Fire, water, ice, have each in turn played their part and exerted their distinctive power in fashioning and moulding this little gem of the ocean into its present shape. The rounded form of the mountain summits which must strike every visitor when he first catches sight of Mona, is due to the fact, that, having been in vast bygone ages elevated by volcanic agency from the depths of ocean, they were at a subsequent period submerged into a sea of an arctic character; and standing in the midst of a current charged with icefloes and icebergs, were ground down, rounded off, and polished. And yet that a much milder climate here also once prevailed, we have evidence in the carboniferous deposits charged with remains of nautili, corals, and tree ferns, the present denizens of seas and lands mostly within the tropics. The rocks of the Isle of Man belong to the palæozoic and to the pleistocene periods. All rocks of the mesozoic and kainozoic periods up to the pliocene strata inclusive, are wanting; and even the uppermost palæozoic beds, viz., the coal measures and the permian sandstones and limestones, are not to be found. The lower palæozoic series is by far the most largely developed, forming the main body of the island. From the Calf of Man to Maughold Head we have a series of schists, forming a mountain range in a rather irregular curved line, whose general direction is from S.W. to N.E., which may be regarded also as the general line of strike. In the almost total absence, as far as yet examined, of any characteristic fossils in these beds, it may be convenient to regard them as lower silurian. They have been disturbed and elevated by the intrusion of granites and porphyritic greenstones. The greenstones may be observed sometimes intrusive, at others apparently imbedded at various points along the mountain ridge from the Sound of the Calf to Maughold Head, more especially at Brada Head, at Rock Mount, near the Tynwald Hill, and at the head of Craig Willis, near the church of St John the Evangelist. They may also be traced along the coast from Langness to Douglas. The granite rises in an enormous dome on the south-eastern side of South Barrule, near the mining district of Foxdale. It also appears at the Dhun River to the N.E. of the Laxey Mines. No doubt the value of these mining districts is greatly enhanced thereby. It has always been found that the metalliferous veins increase in richness as they approach the granitic nuclei. At Foxdale the lead ore in contact with the granite, and in the granite, has yielded more than one hundred ounces of silver to the ton. Where the schists repose upon the granite bosses they are highly metamorphic, and pass by various stages from clay-schist through grauwacke-schist, and mica-schist with garnets, into gneissose-schist and gneiss. No true slate has yet been discovered on the island. The flagstone used for slate seems to have been split in lines of bedding and not of cleavage. At Spanish Head masses of a deep blue clay-schist, slightly clastic, are procured and used largely for lintels. The old red sandstone and conglomerate occurs on the north-western side of the island, at Peel, and also on the south-eastern in the neighbourhood of Castletown, where it crops out around the eastern and northern edge of a basin-shaped depression, occupied by the limestones and shales of the carboniferous era. It rests unconformably upon the upturned edges of the schists, and passes upwards by almost insensible degrees into the beds of limestone. We notice a gradual abstraction of the red matrix around the quartz pebbles of the conglomerate, and a substitution of a grey calcareous matrix instead, with a few of the lower limestone fossils imbedded; ultimately the quartz pebbles die out, and we reach the regular dark limestone beds. The carboniferous series of the Isle of Man may be subdivided into lower dark limestones and shales, comparable to the carboniferous beds of Hook Point in Ireland, and those near Dent and Ulverstone in England; then the upper light-coloured and highly fossiliferous limestones of Poolvash, the equivalents of the scar limestone of Yorkshire and Bolland; and thirdly, the Posidonia schist of Poolvash, the nearest approach in the Isle of Man to the coal measures. This last division contains the so-called Manx black marble, and has been largely wrought into chimney-pieces. It forms the steps of St Paul's Cathedral, London, which were presented by the Venerable Bishop Thomas Wilson. It contains abundantly the peculiar fossil *Posidonia* (whence the name), and some traces of *Calamites*, *Lepidodendra*, and tree ferns. All these beds are greatly intersected and broken up by trap dykes between Langness and Poolvash, the phenomena connected with which may be best observed between the Stack of Scarlett (itself a basaltic pile) and the black marble quarries at Poolvash, and thence along the shore to Kentraugh. The Posidonia schist is actually intercalated with beds of trappean ash; this ash also containing the fossil remains of the animals living in the neighbouring sea at the time when the volcanic eruption took place. A great fault, running from Perwick Bay, Near Port St Mary, in the direction for 5 miles of the granitic boss on South Barrule, cuts off all the beds of the old red sandstone and the carboniferous limestone, the up-cast being on the N.W. side. The whole country on both sides of this fault has subsequently been planed down to one level, and then overspread by the boulder-clay and sands of the *pleistocene* series. The *pleistocene* series of the island consists of boulder-clay, drift-gravel, and sands, which are largely spread out over all the other rocks, and reach far up the mountain-sides, the boulders being found even on the summits of some of the loftiest southern mountains. A large tract of nearly 50 square miles, in the north of the island, is wholly occupied by these beds, for the most part forming a large plain, in which are basin-shaped depressions, covered with beds of peat, but rising also between Point Cranstal, Blue Head, and Jurby Point, to hills upwards of 300 feet in height. In former times (as appears by old maps and records) lakes existed in the depressions in the north of the island, which have since been drained. In still more ancient lakes shell-marl was deposited, and in them we find the remains of the *Megaceros Hibernicus*, or great fossil elk, a fine specimen of which, discovered many years since near Ballaugh, was presented to the Edinburgh Museum by the Duke of Athol. As this was the first almost entire skeleton of the animal discovered and described, it ought rather to have been called Manx than Irish elk. There is no doubt but that the *pleistocene* series occupied at one time the whole bed of the Irish Sea, and united the Isle of Man with the surrounding countries. The rocks immediately under the boulder-clay, where they can be discovered, are distinctly grooved, furrowed, and scratched in a direction generally parallel to the mountain chain; and the boulders consist chiefly of masses of the immediately subjacent rock, themselves scratched and grooved: they have every appearance of having been pushed along in an icy stream. The true boulder clay is very deficient in fossils, and such as occur are, as might be expected, in a very broken and comminuted condition. In hollows in the boulder-clay we find masses of sand and gravel, where the fossils are in a more perfect condition, and present very much of an arctic or sub-arctic character. The drift gravel which overlies the boulder-clay seems to consist of its re-formed material, rounded and worn. If we consider the boulder-clay to have been deposited (as is most probable) during a period of general subsidence of this area, then the drift-gravel marks the period of re-elevation. At certain periods, both of the depression and re-elevation, the present Isle of Man would have exhibited the appearance of a cluster of five or six islands, with strong ice-charged currents flowing between them. The drift-gravel contains pebbles of foreign rock, chiefly Scotch, with some chalk flints, probably derived from the north of Ireland. The most remarkable phenomenon of the boulder-clay which can be noticed, is the occurrence of boulders of undoubted South Barrule granite which have been raised several hundred feet, within the space of 2 miles from the parent source, and perched on the tops of South Barrule, Cronk-na-Irey-Lhaa, and other southern mountains, as well as carried over the ridge in great abundance to the western side of the island. It is not unlikely that being frozen into shore ice, as the mountains were gradually submerged they were stranded higher and higher each succeeding year, and the highest of them will mark the extent to which at least that submergence took place."

The principal minerals are lead and copper ore. The Laxey Mines, near the banks of the Laxey River, produce ores of lead and copper, with much blende (sulphuret of zinc). At Foxdale, between Castletown and St John's, the Isle of Man Mining Company carry on operations to a considerable extent. Lead ore and sulphuret of copper are also found and wrought by the South Manx Mining Company at Brada Head. The mines are rented from the Queen, as lady of the manor, the lessees paying one-tenth part of the produce. The quantities of lead ore, lead, and silver produced in 1852 are as follow:—

	Tons lead ore.	Tons lead.
Isle of Man Mining Company..........	1600	1224
Laxey Mining Company.................	800	600
South Manx Mining Company.........	15	11¼

The average yield of silver from each ton of lead ore is 20 oz., and the produce for the year above named was 36,700 oz.; the value of which, at 4s. 2d. per ounce, was L.7646.

Besides the mines proper, the lime and marble quarries of the S. are worked to a considerable extent; the lime being very valuable, not only for building purposes, but also for agriculture. There is a valuable granite quarry in the region of Foxdale. Rotten-stone and ochre are obtained in the S., near Ballasalla, and a considerable foreign trade is carried on in them. The white spar raised in the Laxey lead mines is valuable.

The climate of the island is noted not only for its mildness but also for its general equality. The mean temperature of the year is 49°·84; of summer, 58°·98; of winter, 41°·57; of July it is 60°·33, and of January 40°·52;—giving the difference between the hottest and the coldest months as 19°·81; between summer and winter as 17°·41.

Before the time of the revestment of the sovereignty of Man in the British Crown, in 1765, agriculture was almost entirely neglected. The herring fishery formed the chief occupation of the peasantry, whilst the women and children cultivated just as much land as would supply the wants of the family and pay the lord's rent.

For the present highly improved state of agriculture, the island has been mostly indebted to the enterprise of English and Scotch farmers, who set a good example in the cultivation of apparently barren land. The dormant energies of the people being thus called forth, they, in many instances, have not been slow to imitate their instructors, and have been amply rewarded with success. Generally speaking, land in a good situation, well cultivated, will give a return in oats of 36 to 45 bushels per acre, barley in the same proportion, and wheat from 25 to 30. In the neighbourhood of the towns, land is let from L.4 to L.5 per acre. The mode of agriculture comprises a succession of crops in the following order:—First, grain crop; second, green crop or summer fallow; third, clover and hay; fourth and fifth, pasture. The proportions of grain sown are,—oats, one-half; wheat, one-fourth; barley one-fourth. Previous to 1845 potatoes were cultivated to a very great extent, and constituted a considerable item of export. Turnips, for which the soil appears to be very favourable, are produced in great quantities; and, from an improved method of cultivation, are allowed, even by the Yorkshire farmers, to be superior to those grown in their own favoured county. Most of the artificial grasses thrive well; the white and red clover, and the common grasses, yield generally good crops, and large quantities of hay are stacked in most of the agricultural districts. The commons, or uncultivated lands, are estimated to form about one-third of the island, including the whole of the mountain-chain. Upon these wastes horses, cattle, and sheep are turned to graze, particularly by the upland farmers. The principal food of these animals during the winter season is the evergreen furze. The native breed of horses is of a small kind, but hardy, useful, and patient of labour, being somewhat similar to those of North Wales. Horned cattle are numerous, but the native breed, being much neglected, have degenerated. Lately, however, the farmers have been improving the breed by the importation of Ayrshire and short-horned cattle. The native breed of sheep is very small, but hardy; their wool is not very long, nor of the finest quality. In the low lands a larger breed has been introduced. There is also a peculiar breed, which is now rapidly disappearing, called, from its mouse-brown colour, the *Loaghtyn*, or *Lugh-doan*. Pigs are bred in considerable numbers.

With respect to the size of farms, the largest portion of cultivated land is held by yeomen, farming from 10 to 150 acres, their own property. In the vicinity of the towns the occupations are generally small. Rent varies from 10s. to L.5 per acre, depending upon the quality of the soil, the means of communication with the town, &c. Though the north possesses an excellent soil, yet the convenience of lime and sea-weed is wholly in favour of the south. Since the abolition of the corn laws in England, little more grain is grown than will suffice for home consumption. Large numbers of cattle, however, are bred for exportation, and are conveyed by steamers to England.

The manufactures and trade of the island are limited, the want of coals being assigned as the principal reason. The staple article of commerce is the products of the fishery; and perhaps the next to that is the mineral treasure.

The peculiar fiscal privileges of the island, as also its influx of visitors, and the large circulation of money they induce, contribute materially to its prosperity and progress; to which may be added the frequent retirement to its shores of opulent residents from the sister isles. Spirited attempts to promote manufactures have, however, been made, and there are now several mills for the manufacture of canvas, woollen cloths, nets, ropes, twine, &c. There are also breweries, tanneries, and soap factories; iron foundries, gas and water companies, &c. Apart from the herring fleet, consisting of about 400 smacks or luggers, the island has a number of small coasting vessels, which are chiefly used for the exportation of grain, ore, &c., and the importation of coals. The latter class of vessels are being gradually superseded by steamers, which ply regularly between Liverpool and Douglas, Ramsey, and Castletown.

The roads of the island are excellent, and are maintained —1*st*, by a system of licenses on innkeepers, grocers, hawkers, &c.; 2*d*, by an impost on carts, carriages, and dogs; 3*d*, by a prescriptive labour duty on housekeepers; and, 4*th*, by a like duty on the quarterlands. The annual fund from all these sources is between L.4000 and L.5000, and it is most ample for the support of all the roads, which are under the management of a highway committee, a surveyor-general, and parochial overseers. Although surveys were made by two companies during the railway mania of 1845, the proposed railway lines for the connection of the four towns of the island were never commenced. Surveys have again been made, with a view to the opening of a railway communication between Douglas and Peel.

The civil government of the Isle of Man is vested in three estates—the Queen in Council, the Governor and Council, and the House of Keys. These last two estates together constitute a court of Tynwald; but the concurrence of the three is essential to every legislative enactment. Acts of the British legislature do not affect the island except it be therein specially included.

The Governor is captain-general of all the troops on the island, and also of the constabulary force. He presides in the council, in all courts of Tynwald or legislature, in all staff of government courts, courts of general gaol delivery, and is *ex officio* sole judge in Chancery and Exchequer courts.

The Council, or staff of government, consists of the lord bishop of the diocese, the attorney-general, the receiver-general, the two *deemsters*, the clerk of the rolls, the water-bailiff, the archdeacon, and the vicar-general, who are also *ex officio* justices of the peace for the island. One or both of the deemsters, the clerk of the rolls, and the water-bailiff, generally sit as assessors in the courts in which the governor presides. The act of the governor and three of his temporal officers is considered a valid act of the governor and council.

The House of Keys consists of twenty-four representatives, who are not elected by suffrage, but are selected by their own body, vacancies being filled up by the House presenting to the governor "two of the eldest and worthiest men of all the Land of Mann," one of whom he nominates, who then takes his seat for life. To them an appeal may be made against verdicts of juries at common law in all cases; and against their decision there is no appeal but to the Queen in Council.

In matters of property the Court of Chancery has the most extensive jurisdiction of any in the island, and is both a court of law and equity. The governor presides, and is assisted by the clerk of the rolls, the deemsters, and the water-bailiff. Like the English Court of Chancery, the proceedings are conducted without the intervention of a jury.

The Exchequer Court takes cognisance of all matters connected with the revenue: proceedings are here carried on for the recovery of all penalties and forfeitures due to the crown, incurred by frauds upon the customs. It passes sentence upon all convicted criminals, and also decides the validity of all titles. This court also determines the right of tithe, which, previously to the act of 1777, was cognisable only by the ecclesiastical courts.

The Common Law Courts for the southern division are held at Castle Rushen, and for the northern division at Ramsey, once in three months. These take cognisance of all actions, real, personal, and mixed, and of all civil matters that require to be determined by a jury. The juries consist of six men, against whose verdict an appeal can be made, in the first instance, to the House of Keys, who possess the high power of affirming, reserving, or altering a verdict at common law.

The Courts of General Gaol Delivery are held twice a-year at Castletown, for the trial of prisoners indicted for criminal offences: the governor presides, attended by the deemsters and the clerk of the rolls. The execution of the sentence of this court in cases of treason, murder, or other capital offences, is never carried into effect until the royal pleasure can be ascertained.

The Deemsters' Courts are of great antiquity. They are held weekly, alternately at Douglas and Castletown, by the deemster for the southern division; and at Ramsey and Peel, or Kirk Michael, by the deemster for the northern division. The judge in this court, by his sole authority, determines in cases of trespass, slander, assault, battery, debts, and contracts; but an appeal can be made against his judgment to the staff of government. The deemsters possess very extensive jurisdiction and high authority; they are the chief justices and the ancient popular magistrates. Their authority is not limited by law to their own divisions, but they have concurrent jurisdiction over the island. They are appointed by the crown, each having a salary of L.800 per annum. On the deemsters every department of the legislature and government depends for advice and direction in all difficult points of law. They take cognisance in a summary manner of all breaches of the peace, and can hold courts instantly on all criminal informations.

The herring fishery, and the boats employed in it, are placed under the charge of the water-bailiff, and he usually holds a court once a-week, to redress grievances, and enforce the regulations of the fishery. He appoints, with a small salary, two intelligent fishermen, who are called admirals, to assist in preserving order. The water-bailiff has also civil jurisdiction in questions of salvage, and takes cognisance of suits in maritime matters, similar to the admiralty courts in England. Against his judgment an appeal can be made to the staff of government.

The High Bailiff's Courts are held weekly in Douglas, Castletown, Ramsey, and Peel, for the recovery of debts under forty shillings.

The Ecclesiastical Courts are,—the consistorial court, in which the bishop, or his vicar-general, or registrar presides, taking cognisance of all matters relating to the probate of wills, granting letters of administration, alimony, church assessments, &c.; and the vicar-general's court, which takes cognisance of all offences against religion, good morals, and the interest of the church, and of all cases not cognisable by the common law courts. The chapter or circuit courts are held for regulating all matters connected with the see, and the general affairs of the diocese.

The magistrates hold regular courts in Douglas fortnightly, and monthly in each of the other towns, for the summary trial of offences for breach of the peace and misdemeanours. These gentlemen are appointed by commission under the Great Seal of England, but their powers are regulated by an insular act of Tynwald. The members of the council and the four high bailiffs are also *ex officio* magistrates, and their clerk is a member of the bar, appointed also by the crown.

A coroner, anciently termed a *moar*, is appointed by the governor to each of the six sheadings or districts of the island, at the Tynwald Court, on the 5th July, annually. He unites in his office the powers possessed by an English coroner, constable, and sheriff's officer. He is both a ministerial officer and a conservator of the peace, and, according to ancient statute, holds his office for one year only.

The laws of the island still retain much of their ancient peculiarity of character, though modified by occasional acts of Tynwald, and rendered in some respects more in unison with those of England. By acts of Tynwald, passed in 1777 and 1813, the criminal code was greatly altered and amended.

The general tenure is a customary freehold devolving from each possessor to his next heir-at-law. The right of primogeniture extends to females as well as males. The interest of a widow or widower, being the first wife or husband of a person deceased, is a life estate in one-half of the lands which have descended hereditarily, and is forfeited by a second marriage; a second husband or second wife is only entitled to a life interest in one quarter. Of the land purchased by the husband, the wife surviving him is entitled to an absolute moiety. By a statute of the year 1777, proprietors of lands are empowered "to grant leases for any term not exceeding twenty-one years in possession."

The annexed Table exhibits the Population of each Parish, and its Relative Increase from 1726 *to* 1851.

The number of houses in 1841 was 8393, and in 1851, 9108; of the latter number 8611 were inhabited.

Language.—The Manx language is a sub-dialect of the Gaelic or ancient Celtic, and it has great affinity to the Erse or ancient Irish language. The natives of the south and west of Ireland, of the Highlands of Scotland, and of the Isle of Man, have but little difficulty in understanding and conversing with each other. This, however, applies only to the pronunciation, for their differences in orthography are such as to perplex even the most learned linguists. The Manx is now only spoken in the north-western parishes, and at a few localities along the western coast, though, with few exceptions, the natives are able to converse in the English language. The services in the parish churches are given alternately in the Manx and English languages, though the Manx is not taught in any of the parochial schools; and it is very probable that in the course of the next generation it will become utterly extinct.

All religious sects are tolerated in Man; but its establishment is connected with the Church of England. It is a diocese in the province of York; but its bishop has not a seat in the House of Peers. His double title of Sodor and Man has its origin in one of those ages so fertile in materials for antiquarian guesswork. Some will have it that Sodor is derived from *Sotor*, the ancient name of a village in Iona; others allege that it is a contraction of the Danish word *Sudoroe*, significant of the Hebrides, which the Scandinavian rovers approached generally from the N., and which are said to have been at one time under the spiritual jurisdiction of the Manx bishops; whilst some, with equal propriety, maintain that it was applicable only to a little island off Peel, and formerly called Sodor, on which a lordly castle once stood, containing the cathedral in which many of its bishops were consecrated, and the cemetery where the dust of most of the wise, and the brave, and the noble of the land was deposited. The bishop is assisted in ecclesiastical matters by an archdeacon, a vicar-general, a registrar, and a sumnar-general. The livings of the clergy arise chiefly from tithes; the patronage, from the bishopric downwards, with the exception of three in the gift of the diocesan, is vested in the Crown. The revenue of the church of Man is a good one, and amply sufficient to maintain all its clergy comfortably, were it only a little more equitably divided. In no part of the world is religious toleration better established than in this island,—not even Britain, with all her boasted religious liberty, excepted,—no license being required, either for the preacher or the place in which he ministers, and liberty of conscience is enjoyed by all. Man is well supplied with the appliances of education. Besides King William's College, there are academies of the very highest class. Its parochial schools have likewise considerably improved during the last few years.

Previous to the Act of Revestment in 1765, the commerce of the island consisted principally of the importing and exporting of contraband goods, the average returns of which exceeded half a million sterling per annum. During that period the island was the grand refuge and storehouse for smugglers, who, as occasion offered, shipped their goods to England, Scotland, and Ireland, to the great injury of the British revenue; the loss to which was then estimated at L.300,000 per annum. After this period the customs of the isle became vested in the British crown, and were placed under the control of a receiver-general, and subsequently, by an act (50th Geo. III.) the regulation and management were transferred to the commissioners of customs in England, which have since remained under their superintendence; and this little island, instead of being a burden to the mother country, now remits about L.30,000 annually to the consolidated fund, after all expenses are deducted.

By the act 7th and 8th Vict., chap. xliii., passed 19th July 1844, commonly called "The Fiscal Bill," the entire revenue of the island is regulated, and has been relieved from many vexatious restrictions.

In 1853–54 several fiscal changes were made by the Lords of the Treasury. Previous to this period British gin and whisky of any description were absolutely prohibited, but they are now admitted, entitled to an inland revenue drawback of 7½d per gallon. Brandy, Geneva or Hollands, and rum, were imported under special license in the undermentioned restricted quantities per annum; and the following table will show the difference between the old and new tariffs:—

	Annual Limitation.	Former Duty.		Present Duty.		
	Gallons.	s.	d.	s.	d.	
Brandy	20,000	4	6	6	0	Without limit or restriction as to quantity imported.
Geneva	20,000	2	6	6	0	
Rum	70,000	1	6	3	8	
Liqueurs	50	10	0	10	0	
Eau-de-Cologne	50	10	0	10	0	
Tobacco	55,000 lb.	1	6	1	6	
Do. manufactured		1	6	4	9	
Cigars	5,000 ,,	3	0	4	9	

To counterbalance the above increase of duties on the luxuries, the following reductions were made on the necessaries of life:—

	Former Duty.	Present reduced Duty.
Tea	1s. per lb.	6d. per lb.
Sugar (Muscovado	1s. 6d. per cwt.	1s. per cwt.
... (Refined)	9s. per cwt.	3s. per cwt.

History.

The little that is known of the early history of the Isle of Man is derived from tradition, from the annals of the surrounding countries, from the Norse and Erse Sagas, and from a record by the monks of Rushen Abbey called the *Chronicon Manniæ*.

The earliest personage mentioned by tradition and history is Mannanan-Beg-Mac-y-Lheirr, from whom the Manx believe the island to have derived its name. He is thus described in the Statute-Book of the island:—"Mannanan-Beg-Mac-y-Lheirr, the first person who held Man, was the ruler thereof, and after whom the land was named, reigned many years, and was a Paynim—he kept the land *under mist* by his necromancy. If he dreaded an enemy, he would cause one man to seem as a hundred, and that by art-magic." He was reputed to be a son of a king of Ulster, and by others a son of Alladius; but both ideas are irreconcilable with history. He appears to be identical with Mainus, the son of Fergus I. of Scotland, who ascended the throne of Scotland 290 B.C. The ancient English historian Nennius, and also Camden, state that Brule or Brude, a Scot, governed the Isle of Man in the reigns of Emperors Aurelius and Honorius, A.D. 395. In 517 Maelgwyn, King of North Wales, who proved a formidable foe to the Saxons in England and the Scots in Man, expelled the Scots, and annexed the island to his Welsh dominions. For this exploit Maelgwyn, who was nephew to the renowned King Arthur, was created a Knight of the Round Table. He was succeeded by his son Rhun-ap-Maelgwyn in 560, from whom in 581 the island was reconquered by Aydun M'Gabhran, King of Scotland, who appointed his sister's son Brennus his viceroy, with the title of "Thane of Man." The Isle of Man appears to have been under the Scotch vice-royalty until about the year 611, when Cadwallon, the Welsh king, appears to have recovered it from the Scots, and to have retained possession of it until 630. Having invaded Northumberland, he was defeated, with immense loss, at the battle of Weddington, by Edwin, the king of the Saxon province of Deira, who, following up his victory, subjugated the isles of Anglesey and Man. Some years afterwards, Cadwallon, obtaining aid from France and Scotland, reconquered the territory which had been overrun by Edwin. Towards the end of the ninth century Harold Harfagra, the son of Halfdan Ivart the Black, the most powerful of the Norse Vikingr, overran and devastated with indiscriminate slaughter the whole of the Western Isles and Man. He appointed as lieutenant of Man and the Isles the jarl Ketil Flatnefr, or Flatnose, who afterwards threw off his allegiance and assumed the sovereignty. He soon afterwards died, and was succeeded by his sons Helgi and Thorstein the Red, the last of whom was expelled in 894. The next king, Mal, was succeeded by his nephew Amlaf or Olave, whose reign was of short duration. In the meantime Harold Harfagra had resolved on uniting the petty kingdoms of Norway into one sovereignty, and after many years of warfare, he effectually succeeded in his object. There is reason to suppose that this act, and his subsequent tyranny, induced the simultaneous emigration of Rollo and his companions to Normandy, of Ingolf to Iceland, and of Orry to the Isle of Man, where they all established independent kingdoms.

After subjugating most of the Western Isles, King Orry arrived in Man, and succeeded in establishing his sway over the island. He was a wise and politic prince, and during his reign the Manx enjoyed undisturbed tranquillity. To him the Manx are indebted for a legislative government. He first divided the island into six sheadings, each of which sent its representatives to the court at Tynwald Hill which was formed in his reign. His descendants continued to rule over Man till 1077, when Godred IV. (Crovan), at the head of a horde of Norwegians, routed the islanders and slew their king, Fingal II. He established himself in the southern district of the island; the remainder he granted to the inhabitants, on the absolute condition of their holding it under him as lord of the whole.

On the death of Godred in 1093, Magnus Barefoot succeeded in obtaining possession of Man, over which he placed the Norwegian jarl Octtar as governor. The inhabitants of the southern district becoming displeased with Octtar, elected Macmarus in his place; a battle in consequence ensued at Santwart (or Sainthill), in the parish of Jurby, and victory was inclining to the party of Macmarus, when the women of the north, rushing to the scene of action, totally changed the issue of the fight, although not till both leaders were slain.

On the death of Magnus, the right of Godred Crovan's line to the kingdom of the Isles was recognised, and Lagman, the son of that conqueror, succeeded to the government; but, from his excessive tyranny, he became detestable to his subjects. He at length abdicated the throne, and undertook a pilgrimage to Palestine, whence he never returned. Olave II. (surnamed Kleining, or the Dwarf), the only surviving son of Godred IV., being then a minor, a regent was appointed, who, by his acts of tyranny and oppression, rendered himself so obnoxious to the people, that he was expelled from the kingdom in the third year of his government. Olave II., who had attained his majority, ascended the throne of his father, and prudently secured peace to his dominions by entering into alliance with the kings of England and Ireland, and by contracting a marriage with Alfrida, daughter of Fergus, lord of Galloway, and grand-daughter of Henry I. of England. His previously quiet reign was disturbed by the pretensions of three natural sons of his brother Harold, by one of whom he was treacherously slain at a conference in 1154. The triumph of the three rebellious nephews was not of long continuance. Godred V. (the Black), Olave's only legitimate son, was recalled from Norway, where he was receiving his education; the whole of the Isles submitted to his authority; and the sons of Harold were delivered to condign punishment. Several attempts were made during his reign to obtain possession of the island, one of which by Somerled, surnamed the Surly, Thane of Argyle, was successful, and Godred had to take refuge in Norway, where he remained till the death of the usurper, on which he regained possession of his throne. His death took place in 1187, in the thirty-third year of his reign. Olave III., his only legitimate son, being then a minor, Reginald, another son, was appointed to the government during his minority. The latter endeavoured to secure to himself the throne by doing homage to John of England, and afterwards by acknowledging the superiority of the pope; but all these efforts were unavailing, and a series of struggles was the consequence, till at length Reginald was slain in a sanguinary engagement in 1229. In A.D. 1237 Olave died in Peel Castle, leaving three sons,—Harold, Reginald, and Magnus; and was succeeded by his son Harold II., who, with his queen and a numerous retinue of nobility, in 1248, were drowned on their return from Norway, where they had been celebrating his marriage with Cecilia, daughter of Hakon, the Norwegian king. His brother Reginald III. assumed the government, and was afterwards slain, with all his party, by the Knight Ivar, a natural son of Godred V. (and brother of the illegitimate Reginald II. the usurper), in 1249. On the death of Reginald III., who left only an infant daughter, his brother Magnus was chosen king. According to usual custom, he went over to Norway, and after two years' attendance at that court, was declared King of the Isles, and had the title confirmed to himself and his heirs. In 1250 John, King of England, landed with an army at Ronaldsway, and proclaimed himself King of Man and the Isles; but his army was defeated and compelled to retreat.

From this time the power of the Norwegian kings began to decline, and that of the Scottish sovereigns to revive. Magnus, threatened by an invasion, did homage to Alexander III. of Scotland, and received from him a charter, by which he held the island from the crown of Scotland. He died in 1265, without issue. In the meantime, Magnus VI. of Norway, as the legitimate sovereign of Man, ceded in 1266 to Alexander III. all his claims and interest in the sovereignty and episcopacy of Man for the sum of 4000 marks, and an annual pension of 100 marks. The widow of Magnus, however (the late King of Man), a woman of haughty and intriguing spirit, succeeded in getting Ivar, the assassinator of her brother-in-law Reginald, placed on the vacant throne; and Alexander in 1270 sent an army, under the command of Alexander Stuart of Paisley and John Comyn, to reduce the island to a state of obedience. After a decisive battle at Ronaldsway, near Derbyhaven, in which 500 of the Manx, with their leader Ivar, were slain, the kingdom was entirely subjugated and annexed to the dominions of Alexander. This monarch, in token of his conquest, substituted the quaint device of "the three legs," which still constitutes the national emblem, for the ancient armorial ensign of the island—a ship in full sail, with the motto, "*Rex Manniæ et Insularum.*" He placed the island under the government of his nobles or thanes, whose repeated acts of tyrannical oppression at length inspired the inhabitants to throw off the Scottish yoke. Bishop Mark (Marcus Galvadiensis), a Scotchman, however, being informed of their determination, obtained their mutual consent to decide the contest by thirty champions selected from each party. The Manx champions were all killed in the contest that took place, and twenty-five of the Scottish warriors shared the same fate. This victory confirmed the conquest of the Scots; the ancient regal government was abolished, and a military despotism established.

During the contentions of Bruce and Baliol, Edward I. of England took possession of the island for a period, while two rival claimants for the throne appeared. One of these was Mary, the daughter of Reginald III.; the other Affrica or Alfrida, a daughter of Olave III., the "Black King of Man," and sister of Magnus (and aunt to Mary, the other claimant). The latter was successful; and she in 1305 conveyed by a deed of gift her right and interest in the island to her husband, Sir Simon de Montacute, whose son Sir William afterwards mortgaged its revenues to Anthony Beck, Bishop of Durham and Patriarch of Jerusalem, to whom the king made a grant of it for life. In 1313 Bruce made a descent on the island, and succeeded in driving out the English. He granted it to his nephew Randolph, Earl of Murray, during whose sway it was overrun and plundered by a numerous body of Irish under Richard de Mandeville.

In the reign of Edward III. Mary Waldebeof, daughter of the previous claimant, and grand-daughter of Reginald III., presented her claims to the sovereignty of the island, and solicited the protection and assistance of that monarch. The king allowed her title, and by giving her in marriage to William Montacute, Earl of Salisbury (the grandson of Sir Simon Montacute and Alfrida), thus united in their persons the rights of the two lines of descendants of Olave the Black to the kingdom of Man. With the aid of the English king, the earl was enabled to expel the Randolphs from the island; and in the year 1344 he was with much pomp crowned King of Man. Thus, to the great joy of the people, was the government restored to its rightful possessors. In the year 1393 the Earl of Salisbury sold to Sir William le Scroop "the Isle of Man, with the title of king, and the right of being crowned with a golden crown."

Sir William le Scroop, afterwards Earl of Wiltshire, being attainted and beheaded for high treason, the island in 1399 was bestowed on Henry Percy, Earl of Northumberland, but he having been attainted and banished, Henry IV. made a grant of it to Sir John Stanley for life. This deed was cancelled, and a new patent passed the Great Seal in 1406, bestowing the island, Peel Castle, and lordship of Man, and the isles appertaining thereto, with all the royalties, regalities, and franchises, with the patronage of the see, on him and his heirs, to be held of the crown of Great Britain, *per homagium legum*, paying to the king a cast of falcons at his coronation.

The lords of the House of Stanley made frequent visits to the island, but governed it chiefly by lieutenants, who occupied the castles of Peel and Rushen, having them fortified with strong garrisons. Various tumults arose, occasioned by the infraction of ancient customs and popular liberty; and in 1422 fourteen persons were drawn by wild horses, quartered and beheaded. Eventually authority was delegated to Henry Byron, whose penetration and policy soon restored order. He remodelled the House of Keys, relieved the people of many oppressive enactments, and by his wisdom and circumspection rendered his regency one of the most popular in the insular history. John Stanley died in 1432, and was succeeded by his son Thomas, who was created Baron Stanley by Henry VI., and died in 1459. Thomas his son succeeded him, and was created Earl of Derby by Henry VII. for the aid he rendered to him with his forces at Bosworth; and he is remarkable in English history as having crowned Henry on that memorable battle-field. This nobleman's son Thomas, the second Earl of Derby, relinquished the title of King of Man, as he preferred "being a great lord, to a petty king." He died in 1522. Edward, the third earl, son of the last-named Thomas, was a great favourite with Henry VIII., and was reputed to have been very rich and munificent; during his time the revenues were confiscated, and the edifice dismantled, of the venerable abbey of Rushen, which was the last of all the monasteries dissolved by the rapacious and sanguinary Henry VIII. He died in 1572, and was succeeded by his son Henry, the fourth Earl of Derby. He died in 1594, leaving two sons, Ferdinand and William, who in time became lords of Man. The title of William was disputed by the three daughters of Ferdinand: with these, however, he effected a compromise; and in 1610 obtained an "act for assuring and establishing the Isle of Man in the name and blood of William, Earl of Derby." He, in 1637, being tired of public life, resigned his dignities to his son James, so celebrated in history as "the great Earl of Derby."

During the civil war the island remained steadily attached to the interests of the king, and was one of the last places that yielded to the authority of Cromwell. After the relief of Lathom House and the battle of Bolton, the noble earl retired to the Isle of Man, where he continued to reside, actively engaged in protecting his interests, until 1651. In that year he again proceeded to England, where he raised a force, joined the royal army, was defeated and taken prisoner at Worcester, and beheaded at Bolton, October 16, 1651. The defence of the island was undertaken by the heroic Lady Derby, who was then in Castle Rushen; but William Christian, the receiver-general, on the appearance of a hostile fleet, surrendered the castle without resistance, to which act of treachery there is little doubt that he had been bribed.

On the decapitation of Earl James, the Parliament granted the island to General Fairfax in consideration of his services, who held it until the Restoration, when it was restored to Charles, the eighth earl (the son of Earl James), in 1660. On the death of Earl Charles in 1672, he was succeeded by his son William, the ninth earl, who took but little interest in his Manx property, and dying without issue in 1702, was succeeded by his nephew James (a younger son of Charles, the eighth earl). At this time the lordship of Man was approaching to dissolution. The leases, which had been granted for three lives, having nearly expired, and no provision having been made relative to their renewal, the neglect of agriculture became so general that repeated seasons of scarcity and famine occurred, and the people were wholly given up to the fishery and the pursuit of the contraband trade. Bishop Wilson energetically drew attention to this injurious system, and his powerful efforts being seconded by a firm but respectful remonstrance from the insular legislature, prevailed upon his lordship to confer in 1703 upon his Manx subjects the Act of Settlement (very justly called the Manx Magna Charta), and which may be considered one of the most important occurrences in the civil history of the island, as by it the lessees of estates were finally established in their possession, and their descent assigned in perpetuity, on the payment of certain fines, rents, and dues to the lords. James died in 1736 without issue, and was the tenth and last earl of the noble and illustrious House of Stanley, who had been sovereigns of the isle for more than 300 years.

The lordship of Man then devolved on James, second Duke of Athol, a descendant of the Lady Amelia Sophia Stanley (the youngest daughter of the noble James, the seventh Earl of Derby). In 1726, in order to put an end to the contraband trade of the island, which had become so extensive as materially to affect the revenue of Great Britain, an act of Parliament was passed authorizing the purchase of all the royalties and revenues of the island; but though many overtures were made by the government, no result followed till after the death of the duke, whose only daughter Charlotte, the Baroness Strange, being married to her cousin John, the next male heir to the dukedom, conveyed to him the lordship of Man in her own right. Proposals for the purchase were revived in 1765, and measures having been introduced into Parliament for the more effectual prevention of the illicit trade of the island, the duke and duchess agreed to surrender the sovereignty and its revenues for L.70,000. They reserved the manorial rights, the patronage of the see, and some emoluments and perquisites, respecting which a misunderstanding arose in consequence of the British government claiming more than the duke and duchess intended by the treaty to relinquish, and therefore a further sum of L.2000 per annum was granted as an annuity to the duchess out of the Irish revenue: the sovereignty of the island thus became vested in the crown of England. By the Act of Revestment the island was more closely united to the parent country, and its prosperity has ever since been progressively advancing, though its original and independent form of government has not experienced any material change. On the ground of inadequate compensation, their son John (the fourth duke) presented petitions to Parliament and the Privy Council in 1781 and 1790, but unsuccessfully, until the year 1805, when an act was passed assigning to him and his heirs, as an additional grant, one-fourth of the revenues of the island, which was afterwards commuted for L.3000 per annum for ever.

In 1825 an act passed both houses of Parliament, at the instance of the lords of the Treasury, authorizing the lords of the Treasury to treat with the duke for the purchase of his remaining interest in the island. The duke being very unpopular at the time, and much dissatisfied with his position in the island, willingly embraced the proposal, and the valuation was left to arbitrators appointed on both sides. These in the year 1829 awarded him the further sum if L.416,114 for his rights in and over the soil, as lord of the manor, as follows :—

For the customs revenue	L.150,000
Rents and alienation fines	34,000
Tithes, mines, and quarries	132,114
Patronage of the bishopric, with fourteen advowsons, the aggregate value of which was L.6000	100,000
Total	L.416,114

Thus was the island, with all its privileges and immunities, ceded to the British government.

MANAAR, an island situate on the N.W. coast of Ceylon, giving name to the gulf which separates Hindustan from Ceylon. The island, which is about 15 miles in length by 3 in average breadth, is separated from Ceylon by an arm of the sea about 2 miles broad, and at low water almost dry, excepting a small channel in the middle, of no greater breadth than about 30 or 40 yards. The distance from the western point of this island to that of Ramiseram is 12 leagues, and the intervening space is occupied by a line of sandbanks called Adam's Bridge, but which, according to a tradition of the Hindus, was constructed by their demigod Ram when he invaded Ceylon. Between these two islands small boats constantly ply, and thus keep open the communication between the two coasts. This island, which was first occupied by the Portuguese in 1560, was taken from them in 1658 by the Dutch, who banished thither their refractory subjects. It was subsequently transferred to the British. A survey of the gulf was completed a few years since, and resulted in the formation of the Paumbaum Passage, the particulars of which will be found under that head. E. Long. 80., N. Lat. 9. 3.

MANACOR, a town in Majorca, is situate in a fertile valley, 30 miles E. of Palma. It is substantially built, with spacious streets and squares; and the chief buildings are,—the palace of the ancient kings of the island, a church, a chapel of ease, two schools, an hospital, &c. Brandy, wine, &c., are produced here, and there is a considerable trade in corn, fruits, cattle, &c. Pop. (1845) 9642.

MANAGUA, or LEON, *Lake of*, a lake in Nicaragua, Central America, between Lat. 12. 16. and 12. 40. N., Long. 85. 40. and 86. 30. W.; 156 feet above the Pacific, and 176 feet above the Atlantic. Length, between 50 and 60 miles; greatest breadth, 35 miles. It is situated on the northern slope of the ridge of hills which traverses Central America, connecting the Rocky Mountains in the N. with the Andes in the S. It is of an irregular shape, and the depth varies from 2 to 40 fathoms. The town of Managua is situate on the S.W. shore, 32 miles S.S.W. of Leon, and consists for the most part of low huts and houses arranged in long streets. It has two churches, one of which stands in the middle of a large square, while the other is distinguished by a white gateway in front. The inhabitants are chiefly the aboriginal natives. They are very industrious, and have great skill in imitating foreign articles. Pop. 12,000.

MANAH, a town of Northern Hindustan, in the district of Kumaon, on the north-eastern frontier. It contains 150 or 200 houses, with from 1400 to 1500 inhabitants, who are above the middle size, stout, and well formed, and seem to be of a race between those of Tartary and Hindustan. The houses are two storeys in height, and constructed of stone covered with small deal planks. During the winters, which are very severe, the inhabitants emigrate to the south. A considerable trade is carried on between this place and Lahdak by means of sheep and goats, which are accustomed to the bad roads on the mountains. They import saffron, borax, gold-dust, musk, &c., and export Benares manufactures, and a few light European articles. E. Long. 79. 32., N. Lat. 30. 46.

MANAYUNK, a town in the county of Philadelphia, state of Pennsylvania, North America, is situate on the left bank of the Schuylkill River, 7 miles N.N.W. of Philadelphia, and 89 miles W. by S. of Harrisburg. The town is irregularly built on the slope of a hill near the river, and the upper part contains several fine houses and churches. It has six Protestant and two Roman Catholic places of worship. There is abundance of water-power at Manayunk, and the town contains about sixteen cotton factories, besides three paper-mills, and other manufactories. The river is crossed by two bridges. Pop. (1853) about 7000.

MANCHA, LA, a territory and province of Spain, in New Castile. The territory of La Mancha comprised part of each of the four provinces of Toledo, Albacete, Cuenca, and Ciudad-Real—the latter almost wholly, whence it is still called the province of La Mancha. It is the second province of Spain in point of extent, containing 663 square leagues of level country. From this circumstance, and the apparent scarcity of water and the want of trees, and from the population being concentrated at various points, instead of covering the country,—the whole province presents to the traveller the arid and cheerless aspect of a desert. The principal river is the Guadiana, which rises about 2 leagues from Villarubia, and enters the province of Badajoz near Castilblanco. Most of the other rivers of the province—the Azuer, Jabalon, Gigüela, &c.—flow into the Guadiana. The Guadalmena has also a course of about 6 leagues through part of La Mancha. No advantage, however, is taken of these and the other streams in the province for irrigation, the inhabitants depending entirely on the rain; a neglect for which they have been frequently visited by famine. Besides the numerous streams, there are few spots where water may not be found a few yards beneath the surface; but neither of these supplies has been turned to good account. This province abounds in valuable mines; those of cinnabar in Almaden were well known to the ancients. In 1844 there were thirty-seven of lead and twelve of copper, and a few of silver. There are, besides, manufactures of saltpetre in several parts; quarries of fine stone at Santa Cruz and elsewhere: the white-chalk or *tierra del viso*, is famous. The agricultural products are,—wheat, barley, rye, various legumes, saffron, &c. A good deal of wine and brandy, but not much oil, is made. Hemp is grown in some districts. The mules reared in La Mancha are considered the best in or out of Spain. There are manufactures of woollen cloths, earthenware, saltpetre, gunpowder, and some other articles. The lace of Almagro is exported to all quarters of the kingdom. Grain is exported chiefly to Murcia, Valencia, and Madrid, in which city also the wine and oil of the province find a market. A so-called university existed in Almagro till 1824, since which time there are only primary institutions in La Mancha; nor are these numerous or well distributed. The province contains ten partidos, with a population in 1847 of 277,788.

MANCHE, LA, a department in the N. of France, forming part of the old province of Normandy, and lying between N. Lat. 48. 35. and 49. 40., W. Long. 0. 43. and 1. 50. It is bounded on the W., N., and N.E. by the Manche or English Channel, from which it derives its name; on the E. by the departments of Calvados and Orne; and on the S. by those of Ille-et-Vilaine and Mayenne. Length, 90 miles; average breadth, 27 miles; area, 2291 square miles. The department is traversed from S. to N. by a range of hills of small height called Cotentin, which branch off from the Armoric ridge, and slope gradually towards the sea on either side. The coast is in some parts rugged and precipitous; but in others there are large tracts of sandy beach. There are several pretty good harbours, of which Cherbourg, La Hougue, Granville, Regneville, Carteret, &c., are the chief. The coast is skirted with many islands, single and in groups, such as Mont St Michel, the Chaussey group, Pelée, Tatihou, and St Marcouf, most of which are fortified and garrisoned. The main island of the Chaussey group is remarkable for its granite quarries, and, except by the workmen in these, it is uninhabited. There are no large rivers in this district, the most considerable being the Vire, which enters La Manche in the S.E., and, after flowing in a northerly direction for about 50 miles, falls into the channel at the boundary between this department and that of Calvados. The greater part of the rocks here are of primary formation; but towards the E., near the banks of the Vire, there are to be found deposits of a more recent origin, such as lias, sandstone, limestone, and slate. The country is in general undulating, the soil rich, and the climate moist and mild. La Manche is very extensively cultivated, and the produce of grain is more than sufficient to supply the wants of the inhabitants. Potatoes, hemp, flax, and fruits, are also among its productions, and more than 22,000,000 gallons of cider are made every year. A considerable portion of the land is laid out in pasturage, which is excellent; and fine breeds of horses and cattle are reared, the former being much prized for military purposes. The quantity of live stock is estimated at 92,000 horses, 210,000 head of horned cattle, 320,000 sheep, and 85,000 pigs. Game and fish also abound. Mining operations are carried on to a large extent in iron, lead, and coal; and there are, besides, quarries of granite, marble, slate, limestone, &c., as well as extensive salt marshes along the coast, which are a source of much wealth. The principal manufacturing employments of this department are the working of iron, zinc, and copper, and the making of woollen and cotton stuffs, of cloth, lace, paper, glass, leather, &c. In many of the coast towns there is a good deal of ship-building; and the commerce with the channel is considerable in the agricultural produce of the country, as well as in the articles of manufacture. The department is divided into six arrondissements, and contains six tribunals of primary instance, and four of commerce; six colleges, one normal school, five superior, and 1225 elementary schools. It belongs to the sixteenth military division, and sends four members to the legislative body. The capital is St Lô. The population in 1851 of the various arrondissements was as follows:—

	Cantons.	Communes.	Inhabitants.
St Lô	9	117	99,099
Coutances	10	138	130,475
Valognes	7	118	92,238
Cherbourg	5	73	85,397
Avranches	9	124	117,032
Mortain	8	73	76,641
Total	48	643	600,882

MANCHESTER,

THE second town of the empire in point of population, and the most important on account of its manufactures, is situate almost at the south-eastern extremity of the county of Lancaster, and is distant 186 miles N.W. by N. from London. The site of the original town was early occupied by a fort, which the Celts, migrating from the Continent, and gradually spreading from the north, planted at Castle Field, upon the bank of the River Irwell. Whitaker, the learned historian of the ancient town, gives this station the name of "*Mancenion*, or the Place of Tents." Possession was taken of it by the Romans about a century after its formation (A.D. 72), and they continued masters of it during three centuries, until their final departure from the island. Several of the great Roman roads, traces of which still remain, centred at this point. The fort subsequently fell into the hands of the Pictish invaders, but after a lengthened struggle, was wrested from them by the Saxons, who repaired the damage to the "Aldport Town," brought the people into due subjection to the lord or *thegn*, whose baronial hall covered the space of the existing Chetham's College, and built the churches of St Mary and St Michael. "Manigceastre," as Hollingworth styles the town, was occupied by the Danes about the year 870; and little is known of its succeeding history until, in the apportionment of territory made by the Norman conqueror, Manchester was assigned to William of Poictou, from whom the lordship of the manor has descended by marriage, hereditary succession, or purchase, through the families of Grelley, De la Warre, West, and De Lacey, to "Mossley of the Hough," whose successor, Sir Oswald Mosley, Bart., was the possessor of the manorial rights and property; but on corporate powers and privileges being obtained by Manchester in 1840, these rights, and much valuable property, were sold by him to the new corporation. The Grelleys, De la Warres, and Wests, sat as barons in Parliament; and Thomas de Grelley granted in 1301 a "great charter of Manchester," which, however, has no existing validity.

The Reformation was violently opposed in Manchester; Collyer, the warden of the "College of the Blessed Virgin," Bradford, and Pendlebury, were zealots in the religious controversies it excited; and Bradford died a martyr. In Elizabeth's reign, Persons and Campion, the noted Jesuits, plotted in these districts; and from Ancoat's Lane, now a densely peopled quarter of the town, one of the Martin Marprelate presses sent forth its stirring missives. The clergy were said to be so hostile to the progress of the Reformation, that the "college" was dissolved in the reign of Edward VI.; in Elizabeth's reign a commissioner's court to promote the Reformation was established; and the most severe measures were taken against recusants, who swarmed in the dungeons of Manchester. In 1584 some were executed, one at Manchester, and their heads exposed on the "college." In the "great rebellion," Manchester took a very prominent part, the anti-monarchical party having the ascendancy. A brawl, which arose between the followers of Lord Strange (afterwards the ill-fated Earl of Derby) and the inhabitants, was magnified into a great battle, and proclaimed in the metropolis as "the beginning of civil warres in England, or terrible news from the north;" Lord Strange being impeached by the Lower House for his conduct in the affair. Subsequently the town was formally besieged by his lordship's forces, but they were driven off; and the troops which had been levied for the defence of the place were engaged in various expeditions, one of which was the noted attack on Lathom House. When the warfare had ceased in England, sequestrators were sent down, who alienated the revenues of the college; presbyteries were established throughout the whole of Lancashire; Manchester was the central point of one "classical division," and the provincial synod met there. In these troubled times the warden Heyrick, a man of eminent endowments, acted a distinguished part.

Passing over another long interval, the people of Manchester are found espousing the cause of the Chevalier St George, for their devotion to whom five of the inhabitants were executed in the town. In 1745 they again stood forth in favour of the young Prince Charles; one of the localities in which the plans for his invasion of the monarchy were concocted being in the immediate vicinity, at Jackson's Ferry, near Didsbury. In the summer previous to his public appearance in Scotland, the prince secretly visited Manchester, and was entertained for a considerable time at Ancoat's Hall, the seat of Sir Oswald Mosley, the lord of the manor. The Pretender's forces entered the town on the 28th and 29th of November. They did not receive a very cordial welcome; and when they marched forward by Macclesfield towards Derby, the prince had enlisted from the inhabitants only about 300 followers, and these chiefly of the lower order. In his subsequent precipitate retreat through Manchester, his reception was less agreeable than before. The "Manchester regiment" were left to garrison Carlisle, which place speedily surrendered to the Duke of Cumberland, and they were made prisoners. Many were sent abroad; some of the leaders suffered decapitation, and their heads were exhibited on the top of the Manchester Exchange.

The later history of the inhabitants is of a more loyal character. They were very active in the American contest, the war of the French revolution, and the more recent struggle with Napoleon, raising many regiments of volunteers, and otherwise affording their aid very freely. The first Sir Robert Peel, then residing near Bury, but who was virtually a Manchester manufacturer, his establishment being in that town, contributed money, and raised a troop of volunteers; and in the year 1798, Peel and Yates subscribed L.10,000 to the "voluntary contribution for the defence of the country." From this period to the close of the war in 1815, the people of Lancashire suffered from dear food, high taxes, and by the abstraction of able-bodied men who enlisted for soldiers; and when peace was restored, the corn laws, and the redundancy of labour consequent upon the disbanding of the army, led to a continuance of distress, as also of dissatisfaction. The distress thus engendered, and the political ferment of the times, gave rise, in August 1819, to the noted "Peterloo" affair, in which a countless mass of people, having assembled for the alleged object of petitioning the House of Commons for a reform of Parliament, and the repeal of the corn laws, was dispersed by the yeomanry and the troops of the line. The Radicalism of these times has since cooled down into a more mitigated species of Liberalism. In 1830–31 many very numerous meetings were held in favour of the Reform Bill; and when it became a law, the electors returned as their representatives to Parliament the Right Honourable C. Poulett Thomson, then vice-president of the Board of Trade, and Mark Philips, Esq., both gentlemen of liberal politics. Manchester had previously sent representatives in early times. In the year 1366 the Sheriff of Lancashire, being required to cause the return of burgesses to Parliament from boroughs of sufficient importance to require representation, reported there was no city or borough in the county willing to accept the burdensome honour, "by reason of their inability, low condition, or poverty." But in Cromwell's time, July 1654, Manchester sent Mr Charles Worsley, and in the next year Mr R. Ratcliffe, to represent her interests.

Manchester has been a place of trade from a very early period. In the most remote antiquity the people traded with the Greeks of Marseilles, and with other foreigners, through Ribchester, then a considerable port on the Ribble, which river is now no longer navigable so far inland. In the reign of Henry VIII. a law was enacted to remove the right of sanctuary from Manchester to Chester, on the ground that it caused the resort hither of idle and dissolute persons, to the injury of the "trade, both in linens and woollens," for which the place was "distinguished," and which gave employment to "many artificers and poor folks," whose masters, "by their strict and true dealing," caused "the resort of many strangers from Ireland and elsewhere, with linen, yarn, wool, and other necessary wares for making of cloth, to be sold there." Camden speaks of the town as "of great account for certain woollen clothes there wrought;" and in the year 1650 the people are described as "the most industrious in the northern parts of the kingdom." The disturbances in France and the Netherlands had tended not a little to the growth of manufactures in the town, by causing the settlement of French and Flemish artisans in Lancashire. Early in the last century it was mentioned as a remarkable fact, that in Manchester and Bolton alone goods to the amount of L.600,000 were annually manufactured. The trade appears, in fact, to have attained to as large a growth as was possible in the then confined state of mechanical knowledge. It was not until an impulse was given to invention, and that splendid series of machines was produced, of which the effects have been so amazing, that Manchester became really a place of commercial eminence and great resort.

The first of these inventions, in point of date, was the water-frame, of which Arkwright, in 1769, claimed to be the originator. In 1770 the spinning-jenny of James Hargreaves was first heard of; and in 1779 Crompton's mule-jenny was invented; while the "throstle" became an important modification and improvement of the water-frame. In 1785 Arkwright took out a patent for improved carding, drawing, and roving machines. The steam-engine of Watt dates about the same time, although there were sundry modifications of it both before and afterwards. The power-loom, for which Cartwright took out his last patent in 1787, but which underwent many changes before it could be considered as a practical machine, completes the list of early discoveries. There were, of course, various inventions subordinate to these. In the beginning of the present century, a machine was constructed which outvied all others in importance; it was the self-acting mule, the invention of Messrs Sharp, Roberts, and Company, of Manchester. Their last patent was taken out in 1830, and there are several millions of spindles at work on the principle of spinning yarn almost independently of human labour. Smith of Deanston, and other inventors, have subsequently contrived self-acting mules, and now the self-acting principle of spinning is fully established, and is applied universally to coarse yarns.

The history of this invention is fraught with instruction to the working-classes. Attention was first directed to the possibility of contriving a self-acting mule, in consequence of the frequency of "turns-out" amongst the spinners, and the intolerable domination which they were enabled to exercise, from the circumstance of a comparatively small class of workmen having it in their power at any moment to suspend the whole trade of cotton-spinning. One "spinner" had three or four young hands immediately dependent upon himself; he had also four or five virtually dependent on him, inasmuch as they being occupied in preparing the raw cotton for him to spin, if he took a fit of idleness or insubordination, the preliminary processes were of course suspended. In the same way, if the spinners as a body became idle, the weavers, and eventually the bleachers, spinners, and printers, were brought to a stand; in fact, the whole cotton trade was locked up, and misery and privation were the immediate and wide-spread results. These considerations induced master spinners to call into play the talent of ingenious men, for the purpose of constructing such machines as would give more stability and regularity to the processes of spinning. The self-acting principle has the virtue of being easily grafted on the older fashioned mules, a third of the value of which is sacrificed in so transforming them.

But the mere discovery of the early machines was of little benefit to the country, so long as they could be restricted in their use at the caprice of the patentee. Accordingly, through the instrumentality of Mr Peel, an association of master manufacturers was formed, and a subscription to take proceedings for setting aside Arkwright's patents was entered into, upon the principle of each spinner paying a shilling per spindle for as many as he used. The original subscription list is still in existence; the number of spindles subscribed for was about 20,000, being not more than a fourth of the number now employed by many large manufacturers. In 1781 and 1785 Arkwright's patents were annulled, and the cotton trade took a gigantic stride. The exports, which in 1701 were only to the value of L.23,253, and in 1780 only L.355,060, had risen in 1781 to L.1,101,457, and in 1800 to L.5,406,501; but gradually expanding, the whole exports of the cotton industry amounted in 1856 to upwards of L.38,000,000. The import of raw cotton, which in 1751 was only 2,976,610 lb. weight, was in 1780 upwards of 6,700,000; in 1790, 31,500,000; in 1800, 56,000,000 lb.; and in 1856, 1,000,021,021,000 lb. weight. In 1787 it was estimated that there were in Lancashire 41 cotton factories, in Derbyshire 22, and in Nottinghamshire 17. In 1790 the number had increased; and in 1817 Mr Kennedy of Manchester calculated that there were 110,763 persons employed in cotton-spinning, and 20,768 horses' power. In 1832 Messrs Greg of Manchester made a fresh estimate, giving the number of operatives employed in the cotton-spinning and weaving mills only of Great Britain, 160,000. In the year 1782 a great panic was excited in Manchester by the announcement that 7012 bags of cotton had been imported between December and April.

In 1788 a meeting was held in Manchester to consider the great depression under which the cotton manufacture was labouring from the "immense importation" of Indian goods; and shortly afterwards the cotton manufacturers of Lancashire, in conjunction with those of Scotland, appointed deputies to obtain an interview with the king's ministers, and solicit permission to erect themselves into a company of traders, with privileges similar to those enjoyed by the East India Company. At this time it was estimated that the cotton manufacture employed 159,000 men, 90,000 women, and 101,000 children,—an exaggerated number. In truth, until the passing of the Factory Act, and the appointment of inspectors and superintendents under its authority, there were no means of ascertaining the number of hands employed either in the whole country or in districts. The number of hands employed in Manchester in 1836 was as follows:—

Various local circumstances have combined to scatter the cotton trade over Lancashire, Cheshire, and Derbyshire. Thus, for example, Preston has become a large depôt of the cotton manufacture, the price of labour and local considerations uniting in its favour; Lancaster, for the same reason, is also rising into manufacturing importance.

The subjoined table shows the difference in the price ot labour at Manchester and Glasgow, the great centres of the cotton trade in England and Scotland, in 1833:—

Age.	MALES.						FEMALES.					
	Number Employed.		Aver. Weekly Wages.				Number Employed.		Aver. Weekly Wages.

Amongst other subjects to which the factory commissioners directed their attention, the health of factory operatives occupied, of course, much of their time, and various modes of test and comparison were adopted. Dr Mitchell, one of the medical witnesses examined, made the subjoined estimate of the amount of sickness yearly amongst various classes of operatives:—

	Days of Sickness.
In the Staffordshire potteries, to the age of 61	9·3 per man.
In silk mills, to the age of 61	7·8
In woollen do..	7·8
In flax do...	5·9
In cotton mills in Glasgow	5·6
East India Company's servants..........................	5·4
Labourers in Chatham dockyard	5·38
In Lancashire cotton mills[1]............................	5·35
Ditto ditto under 16 years of age	3·14

A number of children were also measured, and the result was as under:—

	Inches.
Boys in factories measured	55·28
Ditto not in factories ditto	55·56
Girls in factories measured	54·951
Ditto not in factories ditto	54·976

The commissioners also inquired into the state of education amongst manufacturing operatives, and gave the result of an examination of 50,000 work-people as follow:—

	Proportion in the Hundred.			
	Could read.	Could not read.	Could write.	Could not write.

Upon this subject a more elaborate and careful investigation was made in 1834 and 1835 by the Manchester Statistical Society, from which it appeared that there were in the borough of Manchester 43,304 children receiving education, or 21·65 per cent. of the population; and in the borough of Salford 12,885 children, or 23·4 per cent. Of these there were in Manchester 10,108, and in Salford 3131, who attended only day or evening schools; 10,011 in Manchester, and 3410 in Salford, who attended both day and Sunday schools; and 23,185 in Manchester, and 6344 in Salford, who attended only Sunday schools. It further appears that in Manchester two-thirds, and in Salford twenty-two and a half per cent., of the children between five and fifteen years of age were receiving instruction.

The total quantity of yarn spun in England in 1835 was 248,814,531 lb. Mr Burn estimated the number of spindles employed in producing it at 11,152,990; and, calculating the capital in the usual way, namely, at 17s. 6d. per spindle, it would appear that L.9,758,864 was the amount embarked in the cotton spinning. From the same excellent source is derived an estimate of the value of the goods manufactured, and the yarn and thread spun in 1835.

---

[1] Evidence was given by three surgeons at Bolton and a physician at Stayley Bridge, to the effect that the high temperature of mills is not injurious, if there be proper ventilation; that scrofula is not frequent; that asthma and bronchitis are generated in the card-rooms; that pulmonary complaints are of most frequent occurrence amongst factory operatives; but that they are not more liable to sickness than out-door labourers. It is an established fact, that operatives in factories had an exemption from cholera when it raged in Manchester, which was not experienced by other classes.

In addition to the cotton manufacture, Manchester has likewise a considerable and rapidly increasing trade in silk-throwing and weaving. The mill of Mr Vernon Royle, celebrated throughout England for its thrown silk was established in the years 1819–20, and was the first erected in the district. In 1819 there were in Manchester about 1000 weavers of mixed silk and cotton goods, and 50 of pure silk. In 1823 the number of the former had increased to 3000, and of the latter to 2500. In 1828 there were 4000 of the former class and 8000 of the latter; and in 1832 from 12,000 to 14,000 looms were employed by Manchester houses; and the throwing mills, 12 in number, but of which 2 were not then in operation, gave occupation to about 3600 hands. The state of the silk-throwing trade in 1836 was as follows:—

Summary of Silk Mills in Manchester and the County of Lancaster, 1836.

Township.	Power.		No. of Mills.	12 and under 15.		15 and under 18.		Above 18.		Total.

It was calculated that the Manchester throwsters produced about 8000 pounds of thrown silk weekly, but that the silk looms consumed not less than 24,000 pounds, 8000 pounds of which were derived from the Macclesfield throwsters, and the remainder from Congleton, Sandbach, Newcastle, &c., very little foreign thrown being used in Manchester. The silk manufacturers having their principal establishments in Manchester, were estimated to employ not less than 18,500 looms in the weaving of pure or mixed silk goods; and, taking the usual trade average of four persons to a loom, the silk trade of the district, in all its branches, employed not less than 70,000 persons. By the returns already quoted, it will be seen that throughout Lancashire only 366 power-looms were employed in silk, of which number 306 were in Manchester, and sixty in the adjoining parish of Eccles.

The foregoing statistical information, illustrative of the great industry identified with Manchester and its tributaries of trade, extending from the earliest records chiefly to the year 1836, is retained as historical evidence of the period referred to. From that time to the present (1857) a remarkable steadiness in trade and commerce has prevailed, though distinguished by a most extraordinary increase in production, and consequently by greatly extended business ramifications. The repeal of the corn laws in 1846 gave an impulse to the cotton trade beyond all previous precedent. Employment has since been uniform and abundant. Wages have not been reduced, but on the contrary the earnings of work-people have been generally increased, and especially by the constant and unfluctuating employment afforded them. Bread has been moderately cheap; sugar, tea, coffee, and other necessaries and luxuries, have been abundant, and sold at prices so reasonable that their consumption has vastly extended; and though animal food, with butter, cheese, and milk, may be regarded as comparatively dear, yet to increased demand and consumption may be justly attributed the higher prices which are now paid for these latter articles. The general comforts of the labouring classes have, during the last ten years, been fully equal to any aggregate enjoyment ever previously experienced by them. In factories the hours of labour are by acts of Parliament essentially restricted to sixty per week, and are confined, allowing time for meals, between six in the morning and six in the evening, for five days, whilst at two o'clock P.M. on Saturdays the week's work terminates; the average labour of each day for the whole week being ten hours. This principle of limited labour is by voluntary efforts rapidly extending; bankers, merchants, and traders are closing their establishments at earlier hours than formerly; and there is a general tendency to devote Saturday afternoons to recreation. Wages are now, in the cotton trade, paid very extensively on Fridays, to enable the workers and their families to expend their earnings conveniently and judiciously. With the progress, therefore, of the industry of Manchester, opportunities are afforded to the superior and working classes for recreative amusements, whereby their physical health may be invigorated, and, by the increase of libraries and instructive institutions, their mental faculties may be improved and developed.

Many new manufactures have been introduced into the neighbourhood of Manchester. The production of the textile fabrics in all their combinations of cotton, of silk, of woollen, and of flax, has greatly increased; and mixed materials in various goods have thus formed new fields for industry, and called forth the exercise of skill, taste, and ingenuity in results alike fanciful and attractive. Messrs Houldsworth have, with great advantage, skilfully applied mechanical embroidery to all the fabrications of the manufacturer. Glass-works have been established; and the conversion of iron into steel has become an important addition to the now multifarious sources of employment in this district. With these increased sources of employment, labour finds a steady market. But from the cotton industry chiefly flow the profits which recompense the toil of the labourer, and enhance the capital of the manufacturer and merchant. Manchester is unquestionably the metropolis of this vast industry. Not only in this increasing city are there extensive spinning mills and manufactories, but it has become the general market for almost the whole trade; palatial structures of great magnitude have been erected in it as warehouses; manufacturers have entered largely into mercantile operations; and the merchants finding the mere freighting of vessels inadequate to their business, have in many instances become shipowners. To illustrate the progress of this trade, the following tables, showing the imports and consumption of cotton, have been prepared:—

Table of Imports of Cotton into the United Kingdom.

Of the exact extent of the cotton industry in all its branches no statistics exist. From returns made to government, and from the computations of experienced cotton spinners, the number of spindles in mule and throstle machinery cannot be fewer than 28,000,000; to prepare for which an immense number of scutchers, carding engines, bobbin and fly frames, and other auxiliary machines, are indispensable. The number of weaving looms, by hand and power, is beyond the means of estimation; but the spinning and weaving machines give no idea of the supplemental machinery, of the bleaching, printing, and dyeing works, and other aids of this important trade. In addition to the mills, steam-engines, and mechanism employed, there exist multitudes of cottages and dwellings connected with those establishments. And again, beyond these, the vast warehouses containing manufacturing stores, and those to receive and dispose of finished goods, represent in their occupied state an immense investment. But in approximating to an estimate of the fixed and floating capital invested in this now national industry, the shipping required to convey to our shores the requisite raw materials, and that necessary for dispersing the manufactured products, should be remembered. The working of mines, the traffic in minerals, and the banking operations for this trade, are important items; and the actual employment of mercantile capital will altogether indicate a sum of extraordinary magnitude. So that, in naming one hundred millions of pounds sterling as the total amount of fixed and floating capital employed in connection with the cotton manufacture, the truth will not be exceeded.

The trade and commerce of Manchester and the neighbourhood have been much promoted by the valuable services of the Chamber of Commerce. This institution was founded in 1820, and from its commencement has been a consistent opponent of the corn laws, and of monopolies of every kind. It was the first public body to repudiate protection for manufactures—to call for the abolition of every species of differential duties, and for the repeal of the navigation laws. All questions, however, of a purely political complexion, are strictly forbidden to be entertained, either at the meetings of the board of directors, or at a general meeting of the members. The steady and firm course which it has pursued has earned for it a respect and consideration not surpassed—probably not equalled—by any similar association in existence. Its proceedings attract attention in every commercial community throughout the world. Previously to the repeal of the corn laws the chamber had contended for their entire abolition; but there arose another association, named the Commercial Association, which pleaded only for a fixed duty upon foreign corn, though now happily both these institutions are guided by free-trade principles.

The Anti-Corn-Law League, which so essentially contributed to the recognition of free trade as the basis of domestic and international commercial legislation, was called into existence in this city in 1838, and amongst its early, constant, and most distinguished promoters, have been Sir John Bowring, Richard Cobden, John Bright, George Wilson, J. B. Smith, C. P. Villiers, and the late Sir William Molesworth; but, as a confederation, it ramified over the whole United Kingdom. For the single purpose of overthrowing all obstacles to the free import of corn, its council wisely rejected all overtures which would have diverted its exertions to political or other objects; and greatly to the honour and sagacity of the leaders of the council, the propositions made by the Chartists to induce a common organization to be formed between these two bodies, to procure radical changes in the constitution of the country, were not entertained. At length, in 1846, the legislature, either from truthful conviction of the injustice of those laws, or impelled by the fear of denying the almost unanimous call of the people, finally erased them and the principle of protection from the statutes of the realm. To that eminent statesman, Sir Robert Peel, the people of this manufacturing district, and of the United Kingdom, owe a debt of gratitude for the patriotism and courage which he evinced in assisting to annihilate class legislation; nor will this example be lost upon those who direct the destinies of other nations. With the fundamental changes thus effected in the economical laws of this country, the people at large have enjoyed more prosperity than at any previous time; they have become more attached to their institutions, and their loyalty to their sovereign has never before been exceeded.

Happily, with the extension of trade and commerce in Manchester, there has been developed a desire to promote educational, social, physical, and sanitary improvements. Many attempts have originated here to obtain a national system of elementary instruction for the young, but hitherto without success. The diminution in the hours of labour generally affords more time for self-improvement and kindly intercourse amongst work-people. By the establishment of public parks—the gifts of the rich to the poor—such as the Queen's, Peel's, and Philip's, healthful exercise is more amply afforded, and a link of sympathy between the people and their benefactors is hereby secured. A sanitary association has also been formed.

Grateful for the services of the Duke of Wellington and of Sir Robert Peel, the inhabitants of Manchester have erected to their memories suitable statues, which are placed in the area of the Royal Infirmary. The former is represented by the sculptor Noble as a warrior and senator; and the latter by Calder Marshall as a statesman and patron of the arts of life. As if to prove that commerce still exists in alliance with the fine arts, there was opened in Manchester, in May 1857, an exhibition of the treasures of art, procured exclusively from the resources of the United Kingdom. The Queen and Prince Albert have graciously and generously contributed many of their gems of art, and personally have expressed their warmest solicitude for the success of the exhibition. Patrician and plebeian owners of works of art have rivalled each other in the richness and rarity of their contributions; and a more refining, elevating, and instructive source of gratification cannot be conceived than will probably be afforded by this unique gathering of the curious and beautiful stores of art.

The population of Manchester has had a most amazing growth. The town comprehends several townships, viz., Manchester, Chorlton-upon-Medlock, Cheetham, Ardwick, Hulme, Newton, Harpurhey, Bradford, and Beswick, which form the borough of Manchester; Salford, Pendleton, and Broughton, that of Salford; but they are physically, as well as politically and commercially, *one* town, though having separate local governments. Of the townships of Manchester and Salford, the population was as follows at the decennial periods:—

	Manchester.	Salford.
1801	70,409	13,611
1811	79,459	19,114
1821	108,016	25,772
1831	142,026	40,786
1841	192,403	70,224
1851	228,437	87,514

It is calculated that the population of Manchester, Salford, and their districts, is now not less than 500,000.

The township of Chorlton-upon-Medlock, now filled with factories, was not many years since a desert, and the population has sprung up in a way wholly unprecedented. It was, in 1801, 675 persons; in 1811, 2581; in 1821, 8209; in 1831, 20,569; in 1841, 77,107; and in 1851, 123,806. Property has increased in the same rapid ratio. In 1815 the annual value was L.19,830; in 1835 it was L.58,844. A similar augmentation has taken place in other townships. In Manchester in 1815 the annual value of property was only L.308,634; in 1835 it was L.573,085; and in 1856, L.891,228. In Salford it was, in 1815, L.49,048; in 1835, L.114,769; and in 1856, L.201,042. In Broughton (a township without manufactures) the annual value of lands and buildings was, in 1815, only L.5082; in 1835, L.21,303. In Cheetham (also a township containing only private residences) the value was, in 1815, L.8524; in 1835, L.28,541; and since, these townships have proportionately increased.

Manchester ranks as the first manufacturing town in the empire, and in population it is second only to London. The county is divided into several hundreds, Manchester being situated in the centre of that of Salford, in which there has been an immense increase of population within the present century. The total annual value of property in Salford hundred was, in 1815, L.918,397, and in 1829, L.1,554,314. Of these amounts, L.488,053 at the former period, and L.751,200 at the latter, were comprised in the parish of Manchester, which is divided into thirty-two parishes.

In 1848 Manchester became a bishopric, and Dr James Prince Lee was nominated the first bishop. Under this learned and tolerant divine the church establishment has been judiciously fostered, and its usefulness has been greatly increased.

Manchester, as an old parish, has a parish church, said to have been erected by a Lord Delaware in 1422, out of two old churches built in 1300. It is a fine Gothic structure, 216 feet in length from east to west, and 120 feet in breadth, with a handsome tower. It is richly ornamented in the cathedral style, having on the exterior numerous grotesque figures projecting from the roof, in the taste of the age in which it was built. It has of late years been extensively repaired and beautified in conformity with the original design, and affords accommodation, by its great proportion of free seats, to a numerous congregation. It was made collegiate by the founder, who amply endowed it; and, by the increased value of the property, it became a rich ecclesiastical establishment, with a warden, four fellows, and two chaplains; but since the creation of the see of Manchester, the warden and fellows have been substituted by a dean and four canons, the latter now having each the care of a district church. The only churches more than seventy years old are,—St Ann's, in the square of that name, consecrated in 1765; and St John's, in Byrom Street, opened in 1769. As the town has grown, more churches have been built, and others are now being built. The number of those edifices in which the established forms of worship are observed is now very considerable. They are all handsome, some of them elegant structures, and all in the interior are neatly and appropriately finished. As in other manufacturing towns, the number of those who dissent from the Established Church is very considerable. There are six congregations belonging to the Presbyterian Church, two to the United Presbyterian, and one to the Scotch Church; but the largest division is the adherents to the Roman Catholic Church, consisting for the most part of Irish immigrants employed in the lowest kinds of labour. They have seven places of worship, one of them, in Granby Row, opened in 1820, very handsome and costly, in the Gothic style; and in Salford has been erected a most splendid ecclesiastical structure, which, in truth, may be regarded as a Roman Catholic cathedral. There are about thirty chapels belonging to Wesleyan Methodists of different shades of opinion; the Independents have nineteen places of worship, the Baptists eight, the Unitarians four; and there are several belonging to other smaller sects.

As to the religion of the inhabitants, there are other ascertained facts of a more general nature. The church accommodation in Manchester and Salford consists of about 40,000 sittings, exclusively of the Scotch Kirk; that in the Wesleyan Methodist chapels of about 10,000; Roman Catholic and all other dissenting chapels of about 25,000 sittings. The Sunday schools in Manchester and Salford attached to the various religious communities, and the total numbers instructed by each, are as follows:—

Sunday-Schools in Manchester and Salford.

Denominations.	Number of Scholars.		Total.
	Manchester.	Salford.	
Church of England	18,029	6,716	24,745
Independents	8,443	3,772	12,215
Wesleyans	8,746	2,314	11,060
Wesleyan Association	2,598	856	3,454

Welsh Calvinistic	300	...	300
Roman Catholics	9,650	2,500	12,150
Total	55,236	17,894	73,130

After London, Liverpool, and Dublin, the payments to the post-office in Manchester exceed those of any town in the kingdom. They were for the three years, 1832, 1833, and 1834, respectively, as follows:—L.53,510, 8s. 4d., L.56,287, 16s. 11d., and L.60,621, 12s. 6d. Since that period, the beneficial change effected in the postal arrangements of the United Kingdom, by the introduction of a universal penny postage, has rendered the money receipts of this office no adequate comparative standard for recording the progress of the correspondence generally resulting from the vast increase of trade and commerce in this city; yet in 1856 postage stamps sold at the Manchester post-office, and postages, &c., paid, amounted to L.75,043. The money-orders received and paid at this office in the same year amounted to L.570,506, 15s. 4d.,—thus proving the immense advantage of this banking auxiliary to the poor, as well as to all other classes of the community.

The state of the poor in Manchester, and throughout Lancashire generally, is remarkably comfortable and prosperous. A reference to the returns of the expenditure of poor's rate in Lancashire, and other counties, places this fact quite beyond dispute:—

COUNTIES.	1801.			1811.			1821.			1831.			1841.			1851.

Manchester.

In the township of Manchester, the expenditure exclusively for the poor (deducting the heavy payments to hundred and county rates, and for constables' accounts), was,—

	Per Head on Population.		Per Head On Population.
In 1800–1 …………	6s. 10¾d.	In 1830–31 …………	4s. 3¾d.
In 1811–12 …………	6s. 6¼d.	In 1856 …………	3s. 3½d.
In 1820–21 …………	5s. 3d.		

And in this last year the in-door paupers cost 2s. 3d. per head, whilst the out-door had relief to the amount of 1s. 2½d. for each person so relieved.

The population is taken in the month of April; and as the making up of overseers' accounts takes place on the 25th of March, it was thought better in each instance to take the period nearest to the date of the census, which will account for the years being put in this way.

In the township of Chorlton-on Medlock, almost exclusively a manufacturing suburb, the expenditure has been,—

	Outlay for the Poor.	Proportion to the Population.
In 1826–27…………………	L.317 9 2½	……2s. 8¼d.
In 1830–31…………………	711 12 1	
In 1834–35…………………	945 5 8	

A striking and most important difference appeared in the expenditure of another township (Broughton), in which were few or no manufactures to employ the poor; showing that the poor rates fell much heavier on an agricultural than on a manufacturing population:—

	Outlay for the Poor.	Total Expenditure.	Proportion of the former to the Population.
1827…………	L.444 13 9	L.901 11 9½	…… 4s. 0¼d.
1831…………	320 1 4	856 2 6	
1835…………	186 12 10	796 12 11½	

In connection with these statistics, which are intended to communicate, in as concise a form as possible, a correct view of the condition of the people of the principal manufacturing town of Great Britain, it is important to exhibit some data as to the state of crime in the district; and the following table affords that information in an authentic form.

Statement of the Number of Prisoners Tried and Convicted at the New Bailey Court-House, Salford, in the following Years:—

Years.	Male Felons.	Convicted.	Female. Felons.	Convicted.	Misdemeanours.	Convicted.	Total. Tried.

Discharged……….	59,826	… 11,059 were tried and convicted.
	73,876	… 13,761 were committed for trial.

The towns of Manchester and Salford consist of two boroughs, and are governed by two mayors and a number of aldermen and councillors. The two corporations have distinct municipal powers; but sometimes they co-operate for a great and common object. Manchester has recently supplied itself with excellent water from Woodhead in Derbyshire, and Salford participates in the great advantage of the acquisition. Manchester possesses large gas-works, which are important, inasmuch as the profits accruing from them are expended upon those improvements which tend so much to the health, the comfort, and the ornament of a densely peopled town.

The gigantic undertakings of the celebrated Duke of Bridgewater, who, and his engineer Brindley, may without exaggeration be styled the parents of canal navigation in England, had their centre in Manchester. In succeeding years the example so nobly set was rapidly followed, and Manchester has the advantage of a connection, as direct as canal and river navigation conjoined can afford, with Liverpool, Hull, Goole, London, Lancaster, and indeed all the great seaports and inland commercial towns. It is remarkable that this district should have been the first to manifest the immense importance of railway communication. The history of the Liverpool and Manchester Railway, which was opened in 1830, is familiar to every one; and now (1856) Manchester has complete communication by railways with every part of the United Kingdom.

Manchester has been the birthplace, or abode, or central point of action, of many eminent men. In remoter times the names of Hugh Oldham, Bradford, Booker, Dee (the astrologer), Whitaker (the historian), Byrom (a poet, and the inventor of a system of short-hand), Worthington, Percival, Ogden, Hugh Manchester, Humphrey Chetham, Heyrick, Lord Delamere, Bancroft, Barlow, and Crabtree, hold a prominent place in the history of the town and its connections. Amongst the illustrious of modern days, the commercial metropolis may claim as her own the eccentric Duke of Bridgewater. Mr Thomas Henry, though not born in Manchester, spent his life there; and his attainments as a chemist were brought into beneficial exercise upon the cotton manufacture of the country, in the discovery of most important improvements in the art of dyeing, through the operation of mordants, and by simplifying and applying practically to manufactures the discovery of M. Berthollet in regard to the qualities of oxymuriatic acid, a discovery by which the time occupied in the process of bleaching calicoes has been reduced from days to hours. The first Sir Robert Peel, though born near Blackburn, and a resident of Bury, had his manufacturing establishment in Manchester, and was probably the most extensive manufacturer of his day, excepting perhaps Sir Richard Arkwright. Dr Dalton also, though born in Cumberland, spent his life from the age of twenty-six or thereabouts in Manchester, whither he went originally from Kendal on his appointment to the post of professor of mathematics and natural philosophy at the Manchester New College,—an institution which was subsequently moved to York, but has found a resting-place in Manchester again. The doctor was many years president of the Manchester Literary and Philosophical Society through which many of his most valued discoveries have been communicated to the world. He died in 1844; and now in the infirmary area there is a beautiful bronze statue after Chantrey, to commemorate his discoveries and the esteem in which he was held by his friends and fellow-citizens.

The municipal government of the township of Manchester was formerly committed to a boroughreeve and two constables, who were elected at the court-leet of the lord of the manor, Sir Oswald Mosley, Bart. The boroughreeve exercised the power, without enjoying any of the external distinctions, usually pertaining to a mayor. There was an effective police establishment, under the direction of 240 commissioners elected by the occupants of tenements of a certain annual value; but the local government under the existing corporation is more satisfactory and efficient.

Manchester has a considerable number of associations for the cultivation of science and literature, and the promotion of education. The Royal Manchester Institution ranks first in importance, the inhabitants having expended about L.30,000 in the erection of a noble edifice for periodical exhibitions of paintings, the delivery of lectures, &c., leaving themselves unhappily almost without the means of fulfilling the purposes for which the building was raised. In 1825 a Mechanics' Institution was opened under the presidency of Sir Benjamin Heywood, Bart.,—its area being 738 yards, and the cost L.7000; and 25,000 students have derived the advantage afforded by this institution. Lord Morpeth distributed the prizes of 1833, and Lord Brougham was a visitor in 1835. This institution not being large enough, nor its rooms commodious, a new building was erected in 1855 to supersede the old one, and which was opened by an exhibition of great interest in 1856, under the patronage of Lord Palmerston.

The presidents of the Mechanics' Institution have been, —Sir Benjamin Heywood, Richard Cobden, H. Day, the Right Honourable the Earl of Ellesmere, J. A. Turner; and Oliver Heywood, the son of the first president, is the chairman at the present time (1857). Among the palpable benefits derived from this invaluable institution, the teaching of young females has been of conspicuous advantage. The area of the new building is 942 yards; and the cost of ground, building, and furnishing the several rooms for the use of the members, L.24,000; in diminution of which, there will arise the proceeds of the old institution, valued at, for ground and building, L.7000. The opening exhibition will leave a clear profit of L.4300. It has been visited by 300,000 persons.

The numbers attending the several classes (Christmas 1856) were as follows:—

Female Day Classes.

Morning and afternoon classes for reading, writing, arithmetic, grammar, history, &c.	155
French	25
Pianoforte	39
Dancing	63
Vocal music	17
Dress-making	12
Drawing	26
Wax modelling	5
Total number	342

Male Evening Classes.

Reading, writing, arithmetic, &c.	220
Grammar	82
Geography	44
Mechanical and architectural drawing	130
Landscape and figure drawing	32
Dancing	71
French language	91
German	28
Mathematics	43
Commercial writing	42
Total number	783

There were also, at the above date, 148 members paying 21s. per annum, but not taking advantage of the classes, and 150 life members, having paid in past years L.10, 10s. each.

Very many respectable men,—civil engineers, working mechanical engineers, managers of cotton mills, surveyors, and men holding important confidential offices as cashiers, corresponding clerks, &c., were educated in the classes of the institution.

An excellent natural history society is in a flourishing state; the town boasts a concert hall having an income of L.3000 per annum; there are two schools of medicine, the elder of which (the Pine Street) has attained to considerable celebrity, and which obtained the patronage of King William IV.; and amongst the numerous public libraries is one to which free access is afforded, and which has a large and most valuable collection of books, ancient and modern. This is the library attached to that antique structure, Chetham's Hospital, or the College (now so called), an institution founded two centuries ago by the man whose name it bears, for the maintenance, education, and apprenticing of a number of boys, the offspring of poor parents. Very lately, however, another free library has been established by voluntary subscriptions, chiefly obtained by Sir John Potter, and it is maintained by a municipal rate collected under the act supported by Mr Ewart, M.P. In Salford, also, under the same act of Parliament, has been provided a museum and library, the access to which is likewise free. The Grammar School is another of the ancient foundations which do honour to the town; of late years its funds have so far increased as in 1855 to justify the erection of a second school, in which a course of general education may be gratuitously obtained, whilst the parent building is still devoted to the diffusion of classical knowledge. The school has the advantage of several "exhibitions." The inquiry into the public charities of England includes a very large return of charitable bequests still existent within the hundred of Salford, and of these Manchester has its full share. The town also supports, with a most liberal hand, medical institutions for the cure of almost every disease incident to humanity. At the head of these stands the Royal Infirmary, established in 1752. There are also a Ladies' Jubilee charity, a school for the deaf and dumb, and a blind asylum, which had its foundation in a bequest of L.40,000, made several years ago by Mr Henshaw, a wealthy inhabitant of Oldham; the condition of its application to that benevolent object being, that no part of the sum should be expended in the erection or furnishing of the building, but that the latter should be provided by the inhabitants. After considerable delay, about L.9000 was subscribed, and the asylum has been erected in the outskirts of the city. Other institutions for the relief of the afflicted and the distressed, for the promotion of education and the spread of religion, abound in Manchester, which indeed exhibits a prominent example of the almost profuse expenditure of wealth, hardly acquired, for philanthropic and useful purposes. (T. B—Y.)

MANCHESTER, a town in Hillsborough county, state of New Hampshire, North America, is situated on the left bank of the Merrimack River, 18 miles S.S.E. of Concord, and 59 miles N.W. from Boston. The town is built on a plain at the height of 90 feet above the river, and is regularly laid out. The principal street is wide, and is upwards of a mile in length, parallel to the river. There are four public squares in different parts of the town, some of which are handsomely ornamented. The houses are mostly of brick, but there are many wooden houses, some of which are tasteful structures. The slope from the plateau on which the town stands to the river is occupied by the mills and houses of the workmen. Manchester possesses twelve churches belonging to different denominations; and the educational establishments consist of a high school, two grammar schools, besides others of an inferior class. Manchester has risen into importance quite recently by reason of the water power, which affords great advantages to the manufactories here. Not far from the town the river has a fall of 54 feet in a mile, which is taken advantage of by means of dams and canals, so that it turns many thousand spindles. The town is chiefly remarkable for its manufactures. One company possess four mills, which give employment to 2500 hands, and weave daily 65,000 yards of various stuffs. There are also at Manchester print-works, paper-mills, machine-shops, foundries, and other establishments. In the year 1839 this place only contained fifty inhabitants, but it has rapidly increased since that time. Manchester received its charter in 1846. Pop. (1850) 13,932, (1853) 20,000.

MANCHOORIA, or MANDSHURIA, a large district in the N.E. of Asia, constituting a government of the Chinese Empire, and bounded on the N. by Siberia, on the E. by the Gulf of Tartary and the Sea of Japan, on the S. by Corea and the Yellow Sea, and on the W. by Mongolia. It lies between N. Lat. 42. and 58., and E. Long. 120. and 142., and has an area of between 650,000 and 780,000 square miles. This region is almost entirely surrounded by mountains. The highest of these ranges is the Khing-khan-ula, which separates this district from the table-lands of Central Asia. Its highest summit, Pecha, is more than 15,000 feet above the level of the sea, and is situated near the southern extremity of the range. On the N., Manchooria is separated from Siberia by a lower range, called by the Russians Yablonoi Khrebet, and by the Chinese, Khing-khan Tugwick. Along the eastern coast there extends a very steep ridge, approaching in many places very near to the sea, and which rises to an elevation of 5000 feet. On the S., a prolongation of the Siolki range extends along the frontiers and joins the eastern chain; while the only part which is not surrounded by mountain barriers is towards the S.W., where there is a tract of country of an undulating and hilly character. The region included by these mountains presents towards the S. the appearance of a vast plain, chiefly sandy, but containing many grassy spots which afford good pasturage, and abounding in salt lakes. The northern part of Manchooria, on the other hand, is a country diversified with hills and valleys, almost entirely covered with forests. The country is watered by numerous rivers, of which the principal are,—the Amur and its tributaries, the Seja, the Songari, the Ussuri-ula, &c.; the Tumen-ula, and the Sira Muren, or Liao-ho. Of the soil and mineral resources of this region little is known, since it has never, except in the southern parts, been visited by European travellers; and we are left to the doubtful authority of the Chinese. Wheat, rye, barley, hemp, and cotton, are produced in considerable quantities; and the forests are composed of oak, lime, pine, birch, willow, maple, &c. Rhubarb is also found in considerable abundance, and forms one of the chief articles of export. The domestic animals of this country are for the most part the same as those of Central Asia, with the addition of the rein-deer, which inhabits the country to the N. of the Amur, and the camel, which is found to the S. of that river. Among the wild animals, sables, ermines, bears, wolves, and foxes are the most numerous; and the people are much occupied in hunting them and trading with their skins. The wild sheep and the wild ass are peculiar to this and the neighbouring countries. Tigers are said to occur in Manchooria. Fish and pearls abound in the rivers, and of the latter article the divers send a yearly tribute to the Emperor of China. The climate of Manchooria is cold, and the winters severe, owing to its geographical position and its elevation. The population, with the exception of some Mongolians, belong to a wide-spread race called Tunguses or Tungusians, one subdivision of which comprises the Mandshurs. The Tungusians proper are most numerous to the N. of the Amur, and they are also spread over a considerable portion of Siberia. Their manner of life is erratic; and they subsist chiefly by hunting and by their large herds of cattle. To the race of the Mandshurs the reigning family of the Chinese empire belongs. They began their incursions in 1610, and in the year 1662 they had made such progress as to set upon the throne a monarch of their own nation. The Tungusian language differs from the Mongolian, and though not supposed to have any connection with any other dialect, exhibits a remarkable similarity in many words and expressions to some of the languages of Western Europe; which is the more remarkable as this is the most easterly country in Asia. Manchooria is divided into the three provinces of Shin-king, Kirin, and Tsi-tsi-har, the first of which is governed in the same way as the rest of the Chinese empire; while the other two are under a military despotism. The capital is Kirinoola, or Ghirin-ula, though Moukden, which was formerly the metropolis, is still the most wealthy city; and the other most important towns are Saghalin-ula, Kin-chu, and Fung-whang-ching. An invasion was made into Manchooria by the Russians in the seventeenth century, but although they established themselves for forty years on the Amur, they were at last driven out by the Mandshurs. During the last ten years, however, they have again resumed their attempts, and have made incroachment in the north, having built a fort on the Amur, and several others on the sea-coast. One of these was unsuccessfully attacked by the British in 1855, and another was attacked by some American ships. The population of Manchooria is uncertain, the estimates varying from 2,000,000 to 4,500,000.

MANDAR, MICHEL PHILIPPE, better known under the name of *Théophile*, one of the most enthusiastic characters of the French revolution, was born at Marine in 1759, and studied at Juilly under his uncle J. F. Mandar, a priest of the Oratoire, author of several pleasing poems in Latin and French. Of an active disposition and an ardent imagination, young Mandar embraced the cause of the revolution with great warmth from the commencement, and was early distinguished as a revolutionary orator. When the Swiss regiments under Bezenval endeavoured to check the populace of Paris in their attempt to seize the arms deposited at the Hôtel des Invalides, on the attack of the Bastile, Mandar, at the greatest personal risk, succeeded by a dexterous stroke in persuading the Swiss commander to withdraw his troops, which facilitated the capture of that celebrated prison. Mandar's name, moreover, deserves honourable mention for the mild humanity which he displayed amidst the unscrupulous violence of many of his compeers. On the 3d September 1792, and during the massacres of that memorable month, Mandar, at a meeting in Danton's house, where the chiefs of the revolution sat in council, proposed and boldly stood out for the creation of a dictator to prevent the further effusion of blood, but had the misfortune to see mutual jealousy defeat his humane suggestion. Robespierre exclaimed, "*Garde-t'en bien, Brissot serait dictateur !*" Mandar survived the revolution, but refused office under the imperial government. He occupied his years of retirement with literature, and particularly with translations from the English. His works, political, historical, miscellaneous, and poetical, display great force of thought and energy of expression. He died at Paris in 1823.

MANDARA, an independent kingdom of Western Africa, situated to the south of Bornou. It is overlooked by the central range of the Mountains of the Moon, which attain their greatest elevation to the southward of this territory. Those parts of the mountains examined by Major Denham consist of enormous blocks of granite, both detached and reclining on each other, and presenting the most rugged faces and sides. The interstices and fissures appeared to be filled with a yellow quartzose earth, in which grow mosses and lichens, as well as trees of considerable size. At the base of these mountains, and also at a considerable elevation on their sides, are incumbent masses of decomposed fragments of primitive rocks, recompounded by a species of natural cement. A number of petrified shells were found confusedly mixed with fragments of granite, quartz, sand, and clay, and in some instances imbedded in the rocks. Mandara consists of a fine valley watered by several springs. Amongst the various specimens of the vegetable kingdom are numerous fig trees, and a tree bearing a white and fragrant blossom, resembling the seringi. This kingdom was formerly comprehended within the territory of the Sultan of Karowa, a country bordering upon it to the S.W., but which was wrested from the *kerdy* or pagan sovereign by the neighbouring Fellatahs. His son, however, recovered it from them, and succeeded in keeping possession of it, chiefly, it is said, in consequence of his having embraced the Mohammedan faith. The principal Mandara towns, eight in number, all stand in the valley. The inhabitants of these, as well as of the villages by which they are surrounded, profess Islamism; but the pagans are far more numerous, and their dwellings are seen everywhere in clusters on the sides, and even on the tops, of the hills which immediately overlook the capital. They hold the sultan in great dread, and occasionally propitiate his favour by presenting him with leopard-skins, honey, and slaves, as peace-offerings, besides asses and goats, with which their mountains abound. Mora, the capital of Mandara, is situated in N. Lat. 10. 58. 38., and E. Long. 13. 22., nearly facing the N., under a semicircular ridge of very picturesque mountains. These natural barriers form a strong rampart on every side but one, which, however, the sultan is able so to defend as to bid defiance to the attacks of the Fellatahs. When Major Denham visited this kingdom he found the sultan surrounded by about 500 horsemen, posted on a rising ground about a mile from Delow, the most northern town in Mandara. These soldiers were finely dressed in Soudan *tobes* of different colours (chiefly dark blue, and striped with yellow and red), *bornouses* of coarse scarlet cloth, and large turbans of white or dark-coloured cotton. Their horses were beautiful, being larger and more powerful than any in Bornou, and they were managed with great dexterity. The country to the extreme S. is inhabited by the Musgow people, a rude and savage race. During the visit of the traveller above named, he witnessed the arrival of an embassy of between twenty and thirty individuals of this tribe, mounted on horseback, and bringing 200 of their fellow-creatures, and fifty horses, besides other presents, to the sultan. They were covered only with the skin of a goat or leopard; and round the necks of each were long strings of the teeth of the enemies whom they had slain in battle. Teeth and pieces of bone were also suspended from the clotted locks of their hair, and their bodies were marked with red patches in various places. Dirkullah, a part of this mountain territory, is occupied by Fellatahs, who have their villages strongly fortified, and fight desperately with poisoned arrows, by means of which they on one occasion put to flight the whole force of Bornou and Mandara, though aided by a numerous and well-armed body of Arabs. They are now, however, kept in subjection by the Sultan of Mandara. The common people of this country paint their bodies, wrap themselves in the skins of wild beasts, and subsist chiefly upon fruits, honey, and the fish drawn from large lakes.

MANDAVEE, a large and fortified seaport of Hindustan, in the province of Cutch, situated on the Gulf of Cutch. It trades to a considerable extent with Bombay, Arabia, &c., and its chief articles of export consist of butter, grain, and cotton, for which it receives sugar, pepper, spices, raw silk, piece-goods, &c. E. Long. 69. 26., N. Lat. 22. 50.

MANDAVEE, in Hindustan, a town situated within the presidency of Bombay, and the principal place of a feudal dependency, which, on the demise of its native ruler in 1840, and the failure of heirs in the direct line, lapsed to the paramount power, and was subsequently annexed to the British dominions. It now forms part of the collectorate of Surat. The town is situated on the right bank of the Taptee, in Lat. 21. 11., Long. 73. 20.

MANDEVILLE, BERNARD DE, an author of considerable celebrity in his day, was born about the year 1670 at Dort in Holland. After studying physic at Leyden, where he took the degree of doctor in that faculty, Mandeville came over to England, and commenced practising his profession in London. His success as a physician was not great; but taking to writing, he succeeded in gaining a livelihood, and establishing for himself more than an ordinary share of notoriety. He published his first work in 1709—*The Virgin Unmasked, or Female Dialogues betwixt an Elderly Maiden Lady and her Niece on several Diverting Discourses on Love, Marriage, Memoirs, and Morals*, &c. The work is characterized by anything but delicacy; and whatever may have been Mandeville's design in writing it, no one will be inclined to regard it as calculated to promote female virtue and innocence. In 1711 he published a work, in three dialogues, full of pungent remarks on modern medical practice, entitled *A Treatise on the Hypochondriac and Hysteric Passions*. His short poem of *The Grumbling Hive, or Knaves turned Honest*, appeared in 1714, and was afterwards expanded and published in 1723, under the well-known title of the *Fable of the Bees, or Private Vices Public Benefits*. This work, erroneous as it is in its views of morals and society, is much superior to his first publication; and while written with apparent honesty and sincerity of purpose, it nevertheless exposed its author to no ordinary degree of obloquy, provoking answers and attacks on all sides, and was finally, together with the *London Journal*, a paper to which Mandeville contributed, denounced as immoral, and proscribed by the grand jury of Middlesex. He kept silent till 1728, when he published a second part of the *Fable of the Bees*, to illustrate the design and vindicate the intention of the first.

He published also, in 1720, *Free Thoughts on Religion, the Church, and National Happiness;* and in 1732, *An Inquiry into the Origin of Honour and the Usefulness of Christianity in War*, a work abounding in paradox. He died on the 21st January 1733, in his sixty-third year. Sir John Hawkins, in his *Life of Dr Johnson*, says, that Mandeville was partly supported by a pension from "some vulgar Dutch merchants," and was a frequent guest at the table of the first Earl of Macclesfield. *The Fable of the Bees*, as a satire on men and manners, is just and pleasant, betraying powers of shrewd, happy, subtle observation, by no means common; but as a theory of society and national happiness, it is altogether false and worthless, calculated—however its author might disallow such an inference—to lower the standard of morality, if not to encourage vice and irreligion.

It is his object to show that national greatness depends on the prevalence of fraud and luxury. We find no distinction in his system between luxury and vice; he indeed boldly contends that virtue and vice, and the feelings of moral approbation and disapprobation, have been infused into men by their several governments for the preservation of society, and the maintenance of their own power. Of the host of assailants who attacked Mandeville, the most distinguished were,—William Law, whose remarks on the *Fable of the Bees* have lately been republished, with an introductory essay by F. D. Maurice; Hutcheson, author of *An Inquiry into the Original of our Ideas of Beauty and Virtue;* and Bishop Berkeley in his *Alciphron, or the Minute Philosopher.*

MANDEVILLE, *Sir John de*, the first English prose writer, was born at St Alban's about the beginning of the fourteenth century. Sprung from a good family, he received a liberal education, and seems to have practised for some time as a physician. He set out on his travels in 1322, and repaired to the Holy Land. After serving successively under the Sultan of Egypt and the Khan of Cathay, and journeying through Tartary, Persia, Armenia, India, and other countries, he returned to England about 1355. Not long after this he began to write a narrative of his adventures, which he dedicated to Edward III. He is said to have died at Liège in 1372. Mandeville's work presents a singular mixture of fact and fable. Minutely and candidly he relates his own observations regarding the countries he visited and the men whom he met. With the same truthfulness, whenever an opportunity occurs, he copies descriptions of monsters from Pliny, accounts of miracles from legends, and fables from old romancers. His book, written originally in Latin, was translated by himself into French, and ultimately into English. The original manuscript of this last translation is in the Cotton Library. The best edition is that published under the title of *The Voiyage and Travaile of Ser John Maundeville, knight*, 8vo, London, 1725, and reprinted in 1839, "with an introduction, additional notes, and a glossary by J. O. Halliwell, Esq., F.S.A., F.R.A.S."

MANDING, or MANDINGO, a district in the W. of Africa, bounded on the N. by Fouladou, on the E. by Bambarra, on the S. by Gallonkadou, and on the W. by Gadou, lies between 10° and 14° N. Lat., and between 13° and 16° W. Long. This district is very mountainous, and contains the sources of the Senegal and Niger. The mountains abound in iron, and a considerable quantity of gold-dust is found in the rivers. The country is divided into a number of small aristocratic republics, each village with the territory around it being nearly independent of the rest. The principal of these subordinate states are,—Manding, Bambuk, Bondu, Dentilia, Salum, Barra, Wooly, Yarra, &c. The chief towns are,—Kamalia, the capital, inhabited partly by Mohammedans and partly by Kafirs, Sillidolloo, Kankaba, Dorita, &c. The inhabitants are dark, well-proportioned, and strong; in character, they are good-natured, inquisitive, credulous, and truthful, but are much addicted to thieving. They seldom attain to any great age; but they are not liable to many diseases. The dress of the men consists of a coat, trousers, and sandals, while the women wear pieces of cloth wrapped about their body. Their dwellings are huts built of clay and thatched with rushes. Polygamy is practised among the Mandingoes, but each wife lives in a separate hut. A collection of huts belonging to a single family is called a *surk*, and several of these surks compose a village or town. Weddings are celebrated among the Mandingoes with great festivities. They are fond of music, dancing, and poetry; and they have two classes of wandering bards, who are held in much esteem. The chief occupations of these tribes are agriculture, hunting, fishing, wool-spinning, &c. They also trade in gold, ivory, and slaves; and they are well acquainted with the interior of Africa. In religion they are partly Mohammedans and partly heathens. The *marabouts*, or Mohammedan priests, make long journeys for the purpose of trade, and they are in like manner visited by the priests of other countries. The Mandingoes have spread abroad from their original seat over all the banks of the Gambia, Senegal, and Niger, and they are the most numerous of all the tribes of Western Africa. Their language, which is the richest of all the Negro dialects, is written in Arabic characters, and may be considered the most widely spread, and the most important in a commercial point of view, of all those spoken in Africa.

MANES. See MANICHEISM.

MANETHO, *the Sebennyte*, an Egyptian priest and historian, who flourished under the first Ptolemy, and probably the second also. He wrote a history of Egypt of which an epitome and some fragments remain, and, apparently, at least one other book. The epitome is given by Syncellus from the chronological works of Julius Africanus and Eusebius, of the latter of which there is extant an Armenian version. It is a list of thirty-one dynasties, with the number of kings in each, and generally their names, and with some historical events not always from the original work. The two principal fragments are preserved by Josephus (c. *Apion.*). The epitome does not contain any distinct statement of the complete duration of the dynasties. Such a statement is given by Syncellus, but there is strong reason to think it spurious. The dynasties are generally held to have been partly contemporaneous: hence different arrangements (for which see art. EGYPT). Manetho's accuracy is established by the agreement of the monuments; but much discredit was formerly cast on him by the fraud of an early impostor, now called "Pseudo-Manetho," who wrote the chronological *Book of Sothis*, apparently the groundwork of several false chronologies. Other forgeries seem to have been ascribed to the true Manetho. The extant *Apotelesmatica* may, however, be by a later person of the same name. The best editions of Manetho's remains are in Cory's *Ancient Fragments* (second edition),—nearly complete, but faulty in criticism; in Bunsen's *Egypt's Place*,—a better text, but defaced by some conjectural readings; and in the *Fragmenta Historicorum Græcorum* (Didot), where the arrangement is bad. (R. S. P.)

MANFREDI, *King of the Two Sicilies*, a natural son of the Emperor Frederick II. and of a Lombard lady, was born about 1234. His father dying in 1252, bequeathed to him the principality of Tarentum, and appointed him regent during the absence of his brother Conrad IV. No sooner had Manfredi begun to rule, than the province of Apulia, instigated by Pope Innocent IV., rose in open insurrection. With promptness and vigour he suppressed the rebels; and in the same year in which his government had commenced, delivered into his brother's hands an undisputed sovereignty. He had now become a favourite with the people, but from that very circumstance he was disliked by his brother, and removed from all share in the administration. Yet, in 1254, when the king died, leaving his crown to his infant son Conrad, then in Germany, Manfredi was once more called to the regency. His enjoyment, however, of this dignity was soon interrupted by the inveterate foe of his house, Pope Innocent IV., who forthwith laid him under the ban of excommunication, and, backed by the Guelphs and all the malcontents in the Two Sicilies, advanced to strip him of his power. Deserted by his subjects, and destitute of all means of raising troops, Manfredi was forced to free himself from the sentence of excommunication by agreeing to hold his possessions as an immediate fief of the Holy See. But the pope was unable to rest as long as Manfredi retained any power. Accordingly he began to organize a conspiracy against the liberty and safety of his vassal, which was only frustrated by the latter fleeing from the papal court and repairing for assistance to the Saracens of Lucera, the ever-faithful supporters of his house. With these rallying around him, Manfredi speedily recovered Apulia, and, aided by the death of Pope Innocent IV. in 1254, he received in 1257 the submission of the entire kingdom. In the same year the new pope, Alexander IV., inheriting the hostile spirit of his predecessor, presented the kingdom of the Two Sicilies to Edmund, second son of Henry III. of England, a gift, however, which that prince had not the courage to accept. A report that his nephew Conrad had died in Germany, induced Manfredi in 1258 to assume the title and insignia of king. No sooner had he taken this bold step, than envoys arrived from Conrad's mother to contradict the report, and to demand the resignation of the crown in favour of her son. But Manfredi refused to lay down the sceptre; and so much had his brave defence of his country, his handsome person, and his many accomplishments, endeared him to the hearts of his people, that Conrad's mother was fain to content herself with the promise that her son should be the next occupant of the throne. The elevation of Manfredi only stimulated the enduring enmity of Rome. On the accession of Pope Urban IV. in 1261, he was excommunicated, and his kingdom was placed at the disposal of any European prince who might have the strength to make it his own. At last Charles, Count of Anjou, and brother to Louis IX. of France, accepted the offer; but no sooner had he concluded the bargain with the Roman See than Urban died in 1264. Pope Clement IV. assumed the policy of his predecessor, and after crowning the Count of Anjou with great solemnity, sent him forth in January 1266 against the kingdom of the Two Sicilies. Manfredi, in the February following, encountered the enemy at Benevento. The Apulians passing over to the invaders at a critical moment in the fight, threw the entire Sicilian army into disorder. Manfredi, on seeing the desperate nature of his cause, spurred into the thickest of the battle, and fell covered with wounds. His mangled body was buried under a heap of stones; but ecclesiastical enmity, denying it even this poor resting-place, ordered it to be dragged out and conveyed to a barren valley on the confines of Abruzzo. There, in accordance with the sentence of excommunication, it was interred without any burial rites. Manfredi was the founder of the town of Manfredonia.

MANFREDI, *Eustachio*, an eminent mathematician and astronomer, was born in 1674 at Bologna in Italy. At first he studied philosophy and jurisprudence, and evinced a strong love for poetry, but latterly he devoted most of his time to mathematics and astronomy. He was appointed mathematical professor in the university of his native city in 1698, and surveyor-general of the rivers and waters in 1704. He was chosen regent of Montalto College during the same year, an office which he resigned in 1711 for that of astronomer to the newly established Institute of Bologna. Manfredi was chosen a foreign member of the Academy of Sciences at Paris, and of the Royal Society of London. He died of the stone in 1739. The principal of Manfredi's works are,—*Ephemerides Motuum Cœlestium ab anno* 1715 *ad annum* 1750, in 4 vols. 4to; *De Transitu Mercurii per solem anno* 1723, 4to, Bologna, 1724; and *De annuis Inerrantium Stellarum Aberrationibus*, 4to, Bologna, 1729.

MANFREDONIA, a seaport-town of Naples, province of Capitanata, stands at the head of a gulf of the same name, 19 miles S.W. of the promontory of Gargano, and 20 N.E. of Foggia; N. Lat. 41. 58., E. Long. 15. 56. This town is remarkable for its regularity and symmetry, and although many of the houses are unfinished, and some in a ruinous condition, it has an air of grandeur and uniformity seldom to be met with. The main thoroughfare is a long and wide street, extending from one gate to another; for the city is walled on all sides. Besides two gates to the land side, there are two others leading to the harbour, which is very safe, being protected towards the N. by a small breakwater; but on account of the little depth of water, it is accessible only to the smallest vessels. The town is also defended by round bastions, and by a strong castle, with a ditch and drawbridge, which commands the harbour. The inhabitants are cleanly and industrious, unlike the general character of the Italians, but their numbers have been much reduced by reason of the malaria arising from the neighbouring marshes. Since the recent draining of these marshes, however, the town has become more healthy. A considerable trade is carried on in salt, corn, and fruits, especially oranges. At the distance of a mile to the S.W. stood the ancient *Sipontum*, which was a Roman colony, and of which the only remains are two ancient pillars and a Saracenic church, which is still the cathedral of the archbishop. The modern town was founded by King Manfredi in 1266, and, though called by him *Novum Sipontum*, it afterwards took the name of its founder, which it still bears. Pop. 5000.

MANGALORE, a seaport-town and fortress of Hindustan, on the eastern shore of the Indian Ocean, in the province of Canara. It is large and well built, and is situated on a salt-water lake, which is separated from the sea by a beach of sand, but which communicates with a river. At high water, and in fine weather, ships drawing less than 10 feet can enter it; and there is good anchorage off the mouth of the river in from 5 to 7 fathoms water. The inhabitants are chiefly Mapillas or Moplas (Mohammedans), said to be descended from a colony of Arabians who settled in this place at a remote date. According to some traditions, the first mosque in the country was founded as early as 642, being only a short period after the commencement of the Mohammedan era. More sober authorities, however, refer this event to a period about two centuries later. Fanatical outbreaks on the part of the Moplas have unhappily not been uncommon of late years. Mangalore, though an indifferent haven, was the principal seaport of the territory of Hyder Ali and of his son Tippoo; and here were constructed the ships forming the maritime force of their realm, the teak forests on the slopes of the Ghauts affording abundance of the best timber. The exports consist principally of rice, which is sent to Muscat in Arabia, to Goa, Bombay, and Malabar. The other articles of export are,—betel-nut, black pepper, sandal-wood, cassia, and turmeric; in exchange for which, sugar, salt, and cotton piece-goods are imported. Mangalore was at an early period a great mart of trade, and was resorted to for this purpose by the Arabians. Here the Portuguese had also a factory, which was destroyed by the Arabians. In 1763 the town was taken by Hyder Ali, then the Mysore general; in 1768 it was captured by a detachment from Bombay, but was shortly afterwards retaken by Hyder. In 1783 Mangalore again surrendered to a force from Bombay; and after the destruction of General Matthews' army, sustained a long siege from Tippoo, and was gallantly defended by Colonel Campbell. Upon the conclusion of the peace in 1784, it was restored, and the fortifications were dismantled. In 1799, on the overthrow of Tippoo, it was finally taken possession of by the British. The population, exclusive of the military, has been returned at 11,548 persons. An excellent road from this town to Mercara, a distance of 80 miles, was constructed a few years since, at a cost of L.25,000. Distance from Bombay 440 miles; Seringapatam, 130. E. Long. 74. 54., N. Lat. 12. 52.

MANICA, a small state of Eastern Africa, in the territory of Monomotapa. It is generally mountainous, but is in many parts fertile, and affords pasturage to large herds of cattle. A considerable trade is carried on with the Portuguese, who exchange silk, linen, and iron, for gold, ivory, and copper, which are the chief articles of native produce. The capital of the same name is about eight days' journey W.N.W. from Sofala, in S. Lat. 18. 45., E. Long. 32. 50. Here the Portuguese have a fort with a small garrison of soldiers.

MANICHEISM, a scheme of religious eclecticism, which sprung up in Persia during the third century A.D., and rapidly spread through Syria and Palestine, Egypt and North Africa, as far as Italy, Gaul, and Spain. To its ensnaring philosophy Augustine fell an early victim, but lived to repent his error and to become its most vigorous assailant. The founder of the system was a Persian of the name of Mani, or Manes, a word derived by some from the Hebrew *Menahem*, which signifies the comforter or paraclete, but now generally regarded as from a Sanscrit root signifying a jewel or treasure. The eastern accounts of his history differ widely from the representations given by the writers of the western church, who wrote, however, under the bias of ecclesiastical dislike. From the oriental tradition we learn that he sprang from the sacred race of the Magi, that his family was among the most distinguished in Persia, and that in pomp of dress he always preserved the dignity of his house. He was a proficient in the mathematical sciences, had studied geography, and was an adept in the mysteries of music and painting. All these accomplishments he laid at the feet of the Christian church, and became a presbyter in one of the provinces bordering on Babylonia. His love, however, for the Parseeism of his country soon polluted his Christian teaching, and he was at once excommunicated and exiled for his faith. This latter calamity he owed to the rigour of Sapor I., to whom he unfolded his new gospel of a universal religion, but who was as little inclined to tolerate an inroad on Magianism as the Persian presbyters were to allow the corruption of their Christianity. Mani fled to the east, visiting India and even China, where he studied the principles of Buddhism in order to give a wider basis to his scheme. Returning to a grotto in Turkestan, while his followers believed he had ascended to heaven, he blended together the elements of his religious experience into a gorgeous picture-book, called afterwards the *Ertenki-Mani*, which became the sacred writing of the sect. On the death of Sapor he returned to Persia, when Hormisdas became his patron, and gave him a splendid residence in Susiana. Here he continued to spread his doctrines far and wide; but when Varanes succeeded to the throne, the jealousy of the Magians wrought his ruin. Mani was challenged to a conference, declared to be defeated, and flayed alive as a religious impostor. His skin, stuffed with straw, was suspended over the gate of the city of Sapor as a warning to all his adherents.

In the western accounts there is less both of consistency and romance. According to them, Manicheism owes its origin to a Saracen tradesman named Scythianus, who settled at Alexandria soon after the apostolic age, and bequeathed his doctrines to a pupil called Terebinthus. Soon after the death of his master, Terebinthus went to Babylon, where he assumed the name of Buddas, and pretended to have been born of a virgin, and to have been brought up on a solitary mountain by an angel. An unlucky fall from the roof of his house, however, cut short his days, and a young slave, called Cubricus, decamping with his manuscripts, and with them inheriting his wisdom, earned a more lasting reputation under the assumed name of Manes. At the court of Persia this impostor of the third generation succeeded in forming a school of disciples, whom he instructed and despatched abroad to disseminate his views. Having been unsuccessful in his treatment of one of the princes during a fatal illness, Manes was thrown into prison, and his apostles speedily returned to him with the intelligence that the Christians everywhere counterworked their charms. In the solitude of his dungeon he is said to have studied the Christian Scriptures; and, as soon as he was liberated, he proclaimed himself the promised Paraclete, commissioned to divulge and teach what Christ himself had left unspoken. With this new gospel Manes regained his former favour at the court; and from the Arabion, a castle on the borders of Mesopotamia, he was permitted freely to promulgate his views. A defeat which he suffered in open dispute with the Bishop Archelaus at Cascar, was the signal for his destruction (A.D. 277). Both accounts agree in the mode and circumstances of his death.

Tragic as was the fate of the founder of Manicheism, neither denunciation of divines nor tyranny of kings could daunt the adherents of this intoxicating heresy. In vain they were proscribed and trampled down. From Diocletian to Valentinian III. the severest statutes were framed against them. They were banished from their homes, and extruded from the common privileges of humanity; but after every wave of persecution, they reappeared to defend their doctrines, and the controversy was prolonged far into the middle ages. They are mentioned with as bitter hatred in the Koran as in the pages of Augustine.

It is impossible to give a full account of the Manichean system without expounding the systems from which it borrowed its constituent parts. These are given under separate heads in this work, and it is therefore only necessary here to note the particular dogmas of different creeds which were embraced within its vast eclecticism. These are admirably summed up by Dean Milman:—"From his native Persia he derived his Dualism, his antagonist worlds of light and darkness; and from Magianism, likewise, his contempt of outward temple and splendid ceremonial. From Gnosticism, or rather from universal orientalism, he drew the inseparable admixture of moral and physical notions, the eternal hostility between mind and matter, the rejection of Judaism, and the identification of the God of the Old Testament with the evil spirit, the distinction between Jesus and the Christ, with the Docetism or unreal death of the incorporeal Christ. From Cabalism, through Gnosticism, came the primal man, the Adam Cædmon of that system, and (if that be a genuine part of this system) the assumption of beautiful human forms, those of graceful boys and attractive virgins, by the powers of light and their union with the male and female spirits of darkness. From India he took the emanation theory (all light was a part of deity, and in one sense the soul of the world), the metempsychosis, the triple division of human souls (the one the pure, which reascended at once, and was reunited to the primal light; the second the semi-pure, which, having passed through a purgatorial process, returned to earth to pass a second ordeal of life; the third of obstinate and irreclaimable evil). From India, perhaps, came his Homophorus, as the Greeks called it, his Atlas, who supported the earth upon his shoulders, and his Splenditenens, the circumambient air. From Chaldea he borrowed the power of astral influences; and he approximated to the solar worship of expiring Paganism. Christ the mediator, like the Mithra of his countrymen, dwelt in the sun. From his native country Mani derived the simple diet of fruits and herbs; from the Buddhism of India his respect for animal life, which was neither to be slain for food nor sacrifice; from all the anti-materialist sects or religions, the abhorrence of all sensual indulgences, even the bath as well as the banquet,—and the proscription, or at least the disparagement, of marriage. And the whole of these foreign and extraneous tenets his creative imagination blended with his own form of Christianity; for so completely are they mingled, that it is difficult to decide whether Christianity or Magianism formed the groundwork of the system." (*Hist. Lat. Christ.* ii. 322 ff.)

This cumbrous and complex system had the strange power of evoking a fanaticism as keen as any that the world has ever witnessed; and the fanatical zeal of the sect was stimulated by a severe asceticism and a rigid gradation of ranks. Although the Manichean worship was simple and seldom, their daily life was tinged, in even the most trivial acts, by the presence of superstition. The members of the church were divided into the *perfecti*, or sacerdotal class, and the *auditores*, or catechumens. The head of the priesthood was Mani and his successors in office; and under him twelve apostles, and seventy-two bishops, with presbyters, deacons, and evangelists, formed a descending series of dignitaries. From their founder they received neither temple nor ceremonial. Prayers to the sun, and hymns to the divine principle of light, constituted their vocal worship. They observed the Lord's day, baptized with oil, and celebrated the Eucharist in water mingled with raisins. They rejected animal food, and tolerated marriage only in the inferior orders. Christmas and Good Friday had to them no meaning, as they denied the reality both of Christ's birth and death; but they hallowed annually the day of Mani's martyrdom. The purity of their morals is conceded by Augustine, and probably the eastern Manichees long continued to retain their unblemished character; but in Italy, at least, they soon sank into hopeless degradation.

The best special authorities on the subject of the Manicheans are,—Is. de Beausobre, *Hist. Crit. de Manichée*, Amst. 1734 and 1739; Matter's *Hist. du Gnosticisme;* and F. Chr. Baur's *Manichaische Religions-System*, Tüb. 1831; with Schneckenburger's Review in the *Studien und Kritiken*, iii., 1833.

MANILIUS, Marcus or Caius, a Latin poet, the author of *Astronomica*, an astrological treatise in five books. Regarding the facts of his life, and even his true name, great uncertainty prevails. In different MSS. he is called Manlius and Mallius, and other names slightly varying from each other. Different critics severally suppose him to be the senator Manilius; Manilius called the founder of astrology; and Manilius the mathematician; to all of whom allusion is made by Pliny in his *Natural History*. Yet all these suppositions rest on no surer grounds than the identity of the names, and the fact that all the persons mentioned must have been in a greater or less degree acquainted with astrology. From the internal evidence of his poem, it has been argued that Manilius flourished in the age of Tiberius, although Bentley places him in the Augustan age. The same great critic supposes him to have been a native of Asia, a conjecture that is by no means refuted by the circumstance, that Manilius talks in his poem as if he were a Roman citizen, and were living at the period at which he writes in the Roman capital.

The want of finish, and the abrupt conclusion of the *Astronomica*, evidently indicate that it was left incomplete. As a philosopher, Manilius has shown great talent in using all the astronomical lore of his day in selecting the most sagacious of conflicting opinions, and in starting some conjectures which have been fully verified in modern times. Yet, as a poet, his imperfect taste, and his pointless and inharmonious diction, fall far short of that genius which alone can elevate a scientific subject into the sphere of true poetry. The *Astronomica* was first discovered in manuscript by Poggio in 1416. From this copy the *editio princeps* was printed by Regiomontanus, 4to, Nuremberg, probably about 1472 or 1473. The standard edition is that of Bentley, 4to, London, 1739. A translation into English verse, by Thomas Creech, was published, 8vo, London, 1697, 1700.

MANILLA, capital of the island of Luzon, and of the group of the Philippines, is situated on the E. shore of the bay of the same name, on the S. bank, and near the mouth of the River Pasig; N. Lat. 14. 36., E. Long. 120. 53. The city proper is fortified, being surrounded by walls and a ditch, but it is not sufficiently strong to be able to stand a siege. The walls are about 2 miles in circuit, and the ditch is supplied with water from the River Pasig. The streets are regularly laid out and well paved, the carriage-ways being formed of quartz mixed with loam. The river is crossed by a bridge of ten arches, which leads to the suburb of Binondoc, in which most of the trade is carried on. Although in the town itself the houses are generally built of stone, in the suburbs bamboo is almost solely employed for building purposes. The houses have in general balconies; and the place of glass is supplied by thin plates of shell, which, though not transparent, are very effectual as a defence against the heat. In the suburb of Binondoc the houses are generally raised on wooden posts to the height of 8 or 10 feet, and the suburb in general presents more of an oriental appearance than the town, which is entirely Spanish in character. Binondoc is not so regular and well paved, but it affords a more agreeable variety of appearance. It is intersected by numerous canals, on which boats are continually plying. In the centre of the Spanish city there is a public square about 100 yards in length and breadth, surrounded on three sides by the governor's palace, the cathedral, and the government offices. The square also contains a bronze statue of Charles IV. of Spain, which was presented to the town by Ferdinand VII. in 1824. The town possesses many churches and convents, and a fine custom-house or Aduana. It has also a university, royal college, nautical academy, commercial school, an hospital, and a number of other benevolent institutions. Most of the buildings are of a substantial nature, being composed for the most part of volcanic tufa. Manilla, as seen from the bay, presents a grand and beautiful appearance; it is surrounded by hills, covered with verdure, which slope gradually down to the sea. On the land side of the town there is a large plain, which is set apart for military exercises, and round which there is a fashionable drive called the Calzada. The Pasig is navigable to some distance above the town for vessels of 200 or 300 tons burden; but there is a bar at its mouth with a depth of only 13 feet at low water. The trade of Manilla is considerable; but it is repressed by the restrictions imposed by the Spanish government. The principal articles of export are,—sugar, hemp, rice, indigo, various kinds of woods, tobacco, cigars, coffee, cotton, tortoise-shell, ebony, &c. The tobacco of the Philippines is of first-rate quality; but being a monopoly in the hands of government, its production is very limited. In the royal tobacco factory at Binondoc about 5000 women and 600 men are employed. The imports consist of iron, cotton and woollen stuffs, muslins, handkerchiefs, &c. The trade is principally in the hands of British merchants. The number of the clergy in the town of Manilla is very great; they are said to exceed in number the garrison, which consists of 7000. The religion is Roman Catholic. Manilla, which was formerly a native town, was first settled by the Spanish in 1571. It has been several times injured by earthquakes, especially in 1645, 1762, and 1824. In 1762 Manilla was taken by the

British, but was restored in 1764 to Spain for a ransom of L.1,000,000. Until the year 1809 no foreigners were allowed to trade here; but at that time an English house was allowed to be established, and in 1814 the same liberty was granted to all other nations. It is still, however, the only port in the Philippines at which vessels from Spain or the rest of Europe are permitted to trade. The population of the city itself is from 10,000 to 12,000, but, including the suburbs, the whole number of inhabitants is about 150,000.

MANISA, Manissa, or Manika, a town of Asia Minor, Anatolia, situated on the N. side of Mount Sipylus, 28 miles N.E. of Smyrna. This town was anciently called *Magnesia ad Sipylium*, to distinguish it from another town of the same name on the Mæander. It is chiefly celebrated in ancient history for the victory gained there by the Romans over Antiochus, in the year 190 B.C., after which it fell into the hands of the former. In the reign of Tiberius, it was much injured by an earthquake, but was restored by a grant of money from the emperor. The town is situated on the banks of the Hermus, and is noted as being one of the neatest and cleanest cities in Asia Minor. It contains about thirty mosques, two of which are adorned on the exterior with double minarets, and in the inside with paintings and other articles. The Armenians, Greeks, and Jews, have also their respective places of worship. There is also a fine khan, and a citadel which stands on a lofty rock, and commands an extensive view. The mountains near the town are remarkable for their loadstones, and hence the name "magnet" is supposed to be derived. The surrounding country is rich and productive, especially of saffron, which is exported. The town is the seat of some considerable trade, and many of the inhabitants are employed in the manufacture of cotton and silk goods, and goats' hair shawls. Pop. about 20,000.

MANLII, one of the most ancient and most illustrious of the patrician *gentes* of Rome. Its most notable members were the following:—

Cneius Manlius Vulso, who was curule ædile B.C. 197 (Liv. xxxiii. 25), prætor B.C. 195, and consul B.C. 189. Despatched in this last capacity to settle the affairs of Asia, he waged a successful war against the Galatians, and secured much booty. After remaining in Asia as proconsul during 188 B.C., and effecting the object for which he had been sent, Manlius Vulso set out with his army for Rome; but on his march through Thrace, he was attacked by the natives and stripped of a great part of his plunder. Not without some opposition was he honoured with a triumph in 186 B.C. (Liv. xxxvii. xxxviii. xxxix.)

Marcus Manlius Capitolinus, the deliverer of the Capitol, at an early age carried off the spoils of two enemies, was the first knight to win a mural crown, and gained six civic crowns and thirty-seven marks of distinction. (Pl. vii.) He was consul along with L. Valerius Potitus in 392 B.C.; and two years afterwards he saved the Capitol when on the eve of being captured by the Gauls. For this exploit, according to the ordinary opinion, he was honoured with the surname of Capitolinus. From this time Manlius seems to have fostered a morbid appetite for public applause. Accordingly, in 385 B.C., he placed himself at the head of the plebeians, then groaning under a burden of debts, and roused them to so great a fury against his own order, the patricians, that it was necessary to appoint a dictator. A. Cornelius Cossus, who was raised to this office, threw Manlius into prison, but owing to the clamours of the people, was soon afterwards obliged to release him. In 381 B.C. Manlius was arraigned before the people on the charge of aiming at sovereign power. According to the ordinary account, he overawed his judges during his trial by pointing to the Capitol in the distance, and not until the assembly had adjourned to a spot out of sight of that edifice was he convicted, and sentenced to be thrown from the Tarpeian rock. (Liv. vi. 11–20.) But another tradition represents him to have seized upon the Capitol (Dion. *Frag.* 31); and after holding it for some time, to have been captured and beheaded. (Gell. xvii. 21.) His house was razed to the ground, and the Manlian family decreed that none of its patrician members should take the name of Marcus. Gellius says, that in birth and valour Manlius Capitolinus was second to none, and in personal beauty, exploits, eloquence, and daring, superior to all (xvii. 2). (See Roman History.)

Titus Manlius Imperiosus Torquatus was the son of L. Manlius Imperiosus. When his father was on the eve of being prosecuted for cruelty towards his soldiers and his own son, Titus entered the house of his accuser, the tribune Pomponius, and pointing a dagger to his breast, threatened to strike him dead if he did not forthwith drop the prosecution. In consequence of this bold deed of affection he speedily became popular, and was soon afterwards elected a military tribune. But the greatest feat of Manlius was achieved when he was serving in the army that repelled the invasion of the Gauls in 361 B.C. In the sight of the two hosts on the banks of the Anio, he accepted the challenge of a gigantic Gaul, slew him, and spoiled him of his armour. From a golden chain (*torques*) which he took from the neck of his foe, he was henceforth surnamed Torquatus. (Liv. vii. 4, 5, 10.) After this Manlius was twice raised to the office of dictator, and thrice to that of consul. In his last consulship he conducted a war against the Latins; and while the two armies stood facing each other, he forbade any Roman, on pain of death, to engage one of the enemy in single combat. His own son disobeyed, and suffered the penalty by his father's order. Owing to this extreme severity, the triumph of Torquatus for his victory over the Latins was not attended by the young Romans. (Liv. viii. 3–12.)

Titus Manlius Torquatus was consul along with C. Atilius Bulbus in 235 B.C., when the temple of Janus was closed for the second time. (Liv. i. 19.) His second consulship was in 224 B.C., when, along with his colleague Q. Fulvius Flaccus, he waged a successful war with the Gauls, and was the first that led a Roman army across the Po. (Polyb. ii. 31.) In 216 B.C. he opposed the proposal to ransom the Romans captured at Cannæ. (Liv. xxii. 60.) Soon after this he defeated the Carthaginians in Sardinia, and reduced that island. He was offered the consulship in 210 B.C., but refused it on account of the weakness of his eyes. (Liv. xxvi. 22.)

MANNA, מָן; Sept. μαννά. The name given to the miraculous food upon which the Israelites were fed for forty years, during their wanderings in the desert, is first mentioned in Exod. xvi. It is there described as being first produced after the eighth encampment in the desert of Sin, as white like hoar-frost (or of the colour of *bdellium*, Numb. xi. 7), round, and of the bigness of coriander seed (*gad*). "When the children of Israel saw it, they said one to another, What is it? for they knew not what it was." (Exod. xvi. 15.) In the authorized and some other versions, this passage is inaccurately translated; which, indeed, is apparent from the two parts of the sentence contradicting each other. In the Septuagint the substance is almost always called *manna* instead of *man*. Josephus (*Antiq.* iii. 1, § 6), as quoted by Dr Harris, says,—"The Hebrews called this food *manna*, for the particle *man* in our language is the asking of a question, 'What is this?' (*man-hu*)." Though the manna of Scripture was so evidently miraculous, both in the mode and in the quantities in which it was produced, and though its properties were so different from anything with which we are acquainted, yet because its taste is in Exodus said to be like that of wafers made with honey, many writers have thought that they recognised the manna of Scripture in a sweetish exudation which is found on several plants in Arabia and Persia. The name *man*, or *manna*, is applied to this substance by the Arab writers, and was probably so applied even before their time. But the term is now almost entirely appropriated to the sweetish exudation of the ash trees of Sicily and Italy (*Ornus europæa* and *Fraxinus rotundifolia*). These, however, have no relation to the supposed manna of Scripture. Of this one kind is known to the Arabs by the name of *guzunjbeen*, being the produce of a plant called *guz*, and which is ascertained to be a species of tamarisk. The same species seems also to be called *toorfa*, and is common along different parts of the coast of Arabia, and in the neighbourhood of Mount Sinai. Burckhardt (*Travels in Arabia*, vol. ii., p. 51) says,—"It is from the *toorfa* that the manna is obtained. It is called by the Arabs *mann*. In the month of June it drops from the thorns of the tamarisk upon the fallen twigs, leaves, and thorns, which always cover the ground beneath the tree in the natural state. The Arabs use it as they do honey, to pour over their unleavened bread, or to dip their bread into; its taste is agreeable, somewhat aromatic, and as sweet as honey. If eaten in any quantity it is said to be highly purgative. Ehrenberg has examined and described this species of tamarisk, which he calls *T. mannifera*, but which is considered to be only a variety of *T. gallica*. The manna he considers to be produced by the puncture of an insect, which he calls *Coccus manniparus*. Others have been of the same opinion."

Another kind of manna, which has been supposed to be that of Scripture, is yielded by a thorny plant, very common from the north of India to Syria, and which by the Arabs is called *al-haj;* whence botanists have constructed the name Alhagi. The two species have been called *Alhagi maurorum* and *A. desertorum.* Both species are also by the Arabs called *ooshter-khar*, or "camel's thorn;" and in Mesopotamia, *agool*, according to some authorities; while by others this is thought to be the name of another plant. The *Alhagi maurorum* is remarkable for the exudation of a sweetish juice, which concretes into small granular masses, and which is usually distinguished by the name of Persian manna. Professor Don was so confident that this was the same substance as the manna of Scripture, that he proposed calling the plant itself *Manna hebraica.* These two, from the localities in which they are produced, have alone been thought to be the manna of Scripture. But besides these, there are several other kinds of manna. Burckhardt, during his journey through El-Ghor, in the valley of the Jordan, heard of the Beiruk honey. This is described as a substance obtained from the leaves and branches of a tree called *Gharb* or *Garrab*, of the size of an olive tree, and with leaves like those of the poplar. When fresh, this greyish-coloured exudation is sweet in taste, but in a few days it becomes sour. The Arabs eat it like honey. One kind, called *Sheer-khisht*, is said to be produced in the country of the Uzbecs. A Caubul merchant informed the author of this article that it was produced by a tree called *Gundeleh*, which grows in Candahar, and is about 12 feet high, with jointed stems. A fifth kind is produced on *Calotropis procera*, or the plant called *Ashur*. The sweet exudation is by Arab authors ranked with sugars, and called *Shukur-al-ashur*. It is described under this name by Avicenna, and in the Latin translation it is called *Zuccarum-al-husar*. A sixth kind, called *Bed-khisht*, is described in Persian works on *materia medica* as being produced on a species of willow in Persian Khorassan. Another kind would appear to be produced on a species of oak; for Niebuhr says,—"At Merdin in Mesopotamia, it appears like a kind of pollen on the leaves of the tree called *Ballot* and *Afs* (or, according to the Aleppo pronunciation, *As*), which I take to be of the oak family. All are agreed, that between Merdin and Diarbekir manna is obtained, and principally from those trees which yield gall-nuts." Besides these, there is a sweetish exudation found on the larch, which is called *Manna brigantiaca*, as there is also one kind found on the cedar of Lebanon. Indeed, a sweetish secretion is found on the leaves of many other plants, produced sometimes by the plant itself, at others by the punctures of insects. It has been supposed, also, that these sweetish exudations being evaporated during the heat of the day in still weather, may afterwards become deposited with the dew on the ground, and on the leaves of plants, and thus explain some of the phenomena which have been observed by travellers and others. But none of these mannas explain, nor can it be expected that they should explain, the miracle of Scripture, by which abundance is stated to have been produced for millions where hundreds cannot now be subsisted.

MANNERT, Conrad, a distinguished historian and geographer, was born at Altdorf in Bavaria, in 1756. After completing his studies at the venerable university of his native town, he was appointed professor in the principal educational institution of Nürnberg, a position which he exchanged in 1788 for that of rector of the gymnasium of St Gilles in the same city. In 1797 Mannert was elevated to the chair of philosophy in the university of Altdorf; and in 1808 he went to Landshut in the capacity of professor in ordinary of history, with the title of Aulic Counsellor; but this university being suppressed in 1826, he was appointed professor of geography and statistics at Munich, a situation which he held till his death in 1834.

As a historian Mannert is distinguished for accuracy and critical exactness. He verified his facts with the most scrupulous care, and he has become, in consequence, a weighty authority on geographical and historical subjects.

His *Geography of the Greeks and the Romans* is his most popular work, and is always referred to as a standard authority on that subject. His works are:—*Gesch. der Vandalen*, Leipz., 1785; *Gesch. der Nachfolger Alexanders*, Leipz., 1787; *Miscellanea*, Nürnberg, 1793; *Geographie der Griechen u. Römer*, Leipz., 1788–1825; *Compendium der deutschen Reichsgesch.* Leipz., 1803; *Statistik des deutschen Reichs*, Bamberg, 1806; *Die älteste Gesch., Bojoariens*, Nürnb., 1807; *Kaiser Ludwig IV.*, Landshut, 1812; *Handbuch der alten Geschichte*, Berlin, 1818; *Der Gesch. Baierns*, 1826.

MANNHEIM, or Manheim, the capital of the circle of Lower Rhine, in the grand duchy of Baden, is situated at the confluence of the Neckar and the Rhine, 34 miles N. of Carlsruhe, and 13 N.W. of Heidelberg. The town is built with great regularity and uniformity, and consists of eleven streets running in one direction, and crossed at right angles by ten others. The town is thus divided into squares of houses, which are distinguished not by names, but by numbers and letters of the alphabet. The houses are all two storeys in height, except those at the corners of the streets, which rise to the height of three storeys. The principal thoroughfares are lined with trees, and thus form agreeable promenades. The largest street, called Schrauken, is scarcely half a mile in length. The town was formerly fortified, but the defences were destroyed, and their site is now occupied by gardens and promenades. Both the Rhine and the Neckar are here crossed by bridges of boats, and the latter river has also a suspension bridge. In some of the public places there are fountains, which, however, are not supplied with water, as that is very scarce at Mannheim. The most remarkable building in the town is the magnificent palace of the grand duke, one of the largest in Germany, completed in 1729. It has a picture gallery, a gallery of copperplates, a collection of plaster casts from the most famous ancient sculptures, a collection of antiquities, and a museum of natural history, together with a library containing 60,000 or 70,000 volumes. Mannheim has several Roman Catholic and Lutheran churches, of which that of the Jesuits is the finest. There is a handsome observatory, with a tower 115 feet high, from which a fine view may be had; a theatre, merchants' hall, hospitals, &c. The principal educational institutions are a gymnasium, a botanic garden, and a mercantile school. There are also public baths, a club, and a reading-room. In the neighbourhood of Mannheim there are numerous gardens, and the park connected with the palace has an extent of 200 acres. There are at Mannheim manufactories of tobacco, shawls, linen, and cards; and bleaching and tanning are carried on to a considerable extent. The commerce of this town has been recently very much increased; the principle articles of trade are tobacco, corn, wine, wood, hops, linen, cattle, &c. Its position on two navigable rivers, and its connection by railway with most of the principal cities of Germany, are very favourable to its trade, and render it the first commercial city in the duchy. Till the year 1606 Mannheim was only a village, but at that time Frederick IV., the elector palatinate, enlarged and fortified it. During the Thirty Years' War it was taken by Tilly, Duke Bernhard of Weimar, the French, and the Bavarians. It was afterwards taken by the French in 1688; and in 1720 was made the seat of the electoral court. On the reigning family of Bavaria becoming extinct in 1777, the Elector Charles Theodore succeeded, and removed his court from Mannheim to Munich. It was taken by the French in 1795, by the Archduke Charles in 1799, was again occupied by the French, and finally in 1801, restored to Baden. Pop. (1852) 24,316.
